being emphasised, in some cases, by the presence of fat in the cells at the circumference. In addition to the atrophy of the cells by pressure of dilated hepatic veins, there may be hypertrophy of the interlobular connective tissue, with lymphoid bodies scattered through it. The so-called chronic congestion of the Anglo-Indian is described on p. 897.

SYMPTOMS AND SEQUELÆ.—In slight cases of hyperæmia the liver does not extend much beyond its normal limits, but it may perhaps be felt below the borders of the ribs and across the epigastrium. In severe cases, and especially in passive hyperæmia from obstructed circulation, the organ often attains a considerable size, and is found, on percussion, to extend upwards into the mammary region, downwards nearly to the umbilicus, and across into the left hypochondrium. Its resistance is generally increased, and, in old-standing cases, such as the local condition occurring as the effect of tight-lacing, it may even be hard enough to create the suspicion of malignant disease. There is often, especially in acute cases, tenderness on pressure. The patients do not complain of pain, but of a sense of oppression and fullness in the right hypochondriac and epigastric regions, and of uneasiness from the pressure of clothes, or on lying on the left side. In the most acute cases there is marked functional and general disturbance; a furred tongue, nausea, vomiting at times of bile, bilious diarrhoea, sallowness of complexion, or some amount of jaundice. In certain cases the bile seems to be peculiarly acrid, and causes much griping and distress as it passes downwards, and smarting as it is voided. The urine is high-coloured, and loaded with urates. The patients often complain of headache, are irritable and depressed in spirits, and feel languid and drowsy. When jaundice is present in any marked degree, there is probably catarrh and transient obstruction of the smaller bile-ducts.

There are symptoms indicative of the pulmonary or cardiac affection on which it depends. The complexion is more or less dusky, and there is a certain amount of lividity mixed with the jaundiced hue. The liver may be found to vary in size in accordance with the variations in the conditions which give rise to it. It may sometimes pulsate. Ascites may now become a prominent symptom, while the general dropsy resulting from associated heart-affection may be yielding to treatment.

DIAGNOSIS.—It is only when the congestion is chronic, and the liver hard and resistant, that an erroneous diagnosis may be made; but the previous history of the case, the discovery of a sufficient cause, and the associated general symptoms, will lead to a right conclusion. It might be mistaken for albuminoid disease, and indeed the liver may be really undergoing this degeneration as well.

PROGNOSIS.—This will depend upon the cause, and as it is largely due to disease in the chest, it will be influenced by the nature and stage of such disease.

TREATMENT.—If, as is often the case, the cause is irremediable, treatment can only be palliative. This should include rest; restriction to a bland fluid diet; and the free action of the bowels by a dose of calomel, followed after a few hours by a saline aperient, either in the form of a draught, or of one of the more active mineral waters. A single sufficient dose of calomel, four or five grains, will often rapidly relieve attendant gastric irritation and vomiting, and ensure a free downward discharge

of bile. Should there be much tenderness on pressure over the liver, the application of sinapisms or turpentine stupes, followed by hot poultices, will be beneficial. The portal system must be kept relieved by a dose of Pullna or Friedrichshall water, or by a saline draught, every or every other morning, preceded the previous night by some mercurial preparation, if the secretion seem to require this. Resin of podophyllum may be advantageously substituted for mercury in some cases, but it is uncertain in its action. Its griping effect is counteracted by the addition of a little extract of hyoscyamus or half a grain of extract of cannabis indica, and its action will be quickened by adding a little compound colocynth pill. Other remedies too appear to be sometimes useful, such as taraxacum (aperient and alterative); combined, in subjects of gouty habit, whose urine is more or less charged with lithates, with bicarbonate of potassium, or, in other cases, with diluted nitro-hydrochloric acid. This acid, in torpidity and chronic enlargement of the liver, is one of our most effective remedies. It appears to act by altering and promoting the biliary secretion, and by improving the tone of the digestive organs. It may be used both internally and externally. Ten to twenty drops of the diluted acid of the Pharmacopœia may be given two or three times daily, combined with taraxacum, quinine, or other drug, according to indications. The external use of the acid has been advantageously had recourse to at the Seamen's Hospital for years, either in the form of compress over the abdomen, or by sponging the surface of the body. The fluid is prepared by adding eight ounces of the diluted acid of the Pharmacopœia to a gallon of water at about 98° F. Earthenware or wooden vessels should be used; and all sponges and towels must be well washed in cold water after use, or they will be destroyed by the acid. At times the external use of the acid causes purging; and sometimes severe irritation of the skin. Chloride of ammonium and iodide of potassium must be mentioned as drugs that have been found serviceable in reducing livers enlarged by chronic congestion.

In the hyperæmia resulting from disease of the mitral or aortic valves, or from chronic pulmonary changes, it is sufficient to remark that the chest-symptoms will often be most effectually relieved by treatment directed especially to the liver.

Much benefit will result in many cases of hyperæmia from a course of mineral waters at one of the German or English spas, Marienbad, the springs of Carlsbad, Kissingen, Cheltenham, Harrogate, &c. A more detailed notice of the different spas and waters in relation to hepatic affections will be found under other articles. See LIVER, Functional Disorders of; and MINERAL WATERS.

JAMES F. GOODHART.

LIVER, Inflammation of (including ACTIVE HYPERÆMIA).—SYNON.: Hepatitis; Acute Congestion of the Liver; Fr. *Hépatite Aiguë*; Ger. *Acute Leberentzündung*.

In this article hepatitis and acute congestion of the liver will be treated as one disease, suppurative hepatitis being dealt with separately (see p. 882). It may be said that hepatitis is only an advanced stage of acute hyperæmia or congestion, and this is probably what is meant when cases are returned, as they often are in Army returns, as hepatitis.

Active hyperæmia of the liver is divided into two

varieties, acute and chronic, the latter form, the so-called 'tropical liver,' being due to a persistence of the causes which lead to the acute condition.

ÆTIOLOGY.—Though far from unknown in cold countries, acute congestion of the liver is especially common among Europeans who have migrated to the tropics, and there continue their old habits of life under very different climatic conditions. There is also a form of hyperæmia of the liver which is purely physiological, occurring especially in Europeans near the beginning of their life in the tropics. It is due to the diminished lung-metabolism, the great heat, the less active habits (induced by the heat), and the rich food, for the appetite is stimulated rather than reduced on first arrival in a hot country. This state of physiological hyperæmia may remain stationary, but is very prone to pass into a pathological state from some slight exciting cause, such as a cold bath, a wetting, the fitful pulling of a punkah during sleep, a sudden storm at night, a surfeit of food, an excess of wine taken at a dinner-party, or a chill, especially after polo or tennis. Such causes can produce a very acute congestion or even a hepatitis. If such exciting causes are repeated, or if a patient persists in dietetic or alcoholic excess, or does not take sufficient regular exercise, this state passes gradually into that of chronic engorgement.

Another cause which renders the affection common in warm countries is the influence of repeated attacks of malarial fevers. All attacks of malarial fever lead to the congestion of the internal organs, especially of the liver and spleen, and if these attacks are frequently repeated and not properly treated, they result in a well-marked form of hepatic cirrhosis, ultimately followed by dropsy and all its attendant evils. See *MALARIA*.

The following figures show how much more common hepatitis and hyperæmia of the liver are among Europeans in India than among the natives, thereby also showing the influence of the dietetic and other climatic conditions as factors in their causation. In ten years (1889-99) there were 12,461 admissions for hepatitis and congestion of the liver in the British Army in India, of which the average strength was 68,950, while in the Native Army (average strength 127,000) there were only 1,826 admissions for these complaints; that is, while the British ratio was 18 per thousand, it was only 1·4 among the native sepoys. As regards the influence of alcohol, while there is no doubt that alcoholics suffer largely from hepatic congestion, moderate drinkers and even total abstainers are by no means exempt from this disease.

The life of the British soldier in the long Indian day is in itself conducive to such attacks—parades at early dawn, work over by 9 A.M., confinement in a crowded barrack, with the hot air pouring in through the too often open door, the feebly pulled punkha, the heavy midday meal, the long hours spent lying on a bed, and the evening parade, followed by great thirst, too often quenched by large draughts of beer. There can, however, be no doubt that the frequency of these affections in India has been much reduced during recent years. Bryden's statistics for hepatitis and liver-abscess in the years 1871 to 1876 gave a ratio of admissions to hospital of 55 per thousand; whereas the figures for the same affections for the past ten years (1890-99) show a very much reduced ratio, viz. only 18 per thousand. This change for the better is to be attributed to the improvements in the habits of Euro-

peans in India during the past quarter of a century. The Anglo-Indian of to-day is, as a rule, a temperate man, and probably consumes in a day much less alcohol than the average city-man at home. His chief drink now is whisky, well diluted with aerated water and a block of ice; light German beer, light French or Italian wines, very different in potency from the brandy and heavy ports and sherries of a generation ago.

The same influences have been at work in amending the surroundings of the British soldier in India. More attention is paid to the cooking and the quality of his food; the coffee-shop has to a large extent replaced the canteen; rational amusements are now provided which supply him with regular exercise; and the barracks are airy and better ventilated, and provided with punkhas. The Army Temperance Association has made great strides among the rank and file. Nearly every regiment in India has its own 'soda-water' machine, and aerated waters are sold to the soldiers at an almost nominal cost. That these hepatic affections are much rarer among women and children (European) in India is no doubt due to their quiet indoor life and their lesser indulgence in excess of food and alcohol.

No one has yet given a satisfactory explanation of the lesser prevalence of liver-diseases among Europeans in the West Indies. The British civilian or soldier does not change his habits when he goes to the West rather than the East Indies, yet there seems to be little doubt that liver-affections are much less frequent there than in the East Indies. It may be that the oceanic climate of the West Indian islands has some influence; the sea-breezes temper the great heat; and in no part of the West Indies is the heat so fierce as that of the Punjab, Central India, or Madras.

In the Army returns many cases are returned as hepatitis which are either acute hyperæmia or an incipient stage of hepatic suppuration. Some writers of the French school who carry the dysenteric origin of liver-abscess too far, and ignore its comparatively rare occurrence among natives, among whom dysentery is so common, see a 'congested state of the liver' in every autopsy on a case of dysentery. This the present writer cannot admit, nor can he agree with Kelsch and Keiner in tracing every congestion of the liver to either dysentery or malaria.

ANATOMICAL CHARACTERS.—The liver is uniformly enlarged, and its capsule distended and shining. On incision blood, usually of a deep red colour, oozes out freely. The hyperæmia is not limited to the centre of the lobule. Microscopically the lobules may show signs of fatty change.

SYMPTOMS.—The symptoms vary within wide limits, especially with the degree of acuteness. In slight congestion a smart attack of diarrhœa, with copious dark-coloured stools, is nature's own method of relief, and often the only important symptom. In the more severe cases there is probably pain in the side, and a feeling of weight or fulness in the hepatic region, felt especially when lying on the left side. The degree of general disturbance varies much. The tongue is furred, or has a brown line down its centre, and is indented at the edges. A bitter taste in the mouth is often complained of, the urine is scanty and high-coloured, and the bowels are constipated or irregular. There may be one or two degrees of pyrexia. A pain in the right shoulder, headache, and depression of spirits are

common, and drowsiness after meals is sure to be noted. In the still more acute cases (those usually called hepatitis) all the symptoms are more pronounced, the temperature rises to 102° F. or thereabouts, palpitations are not uncommon, and the patient may complain of having had bad dreams.

In the chronic form, the so-called 'tropical engorgement of the liver,' the liver is uniformly enlarged and painful on pressure. The superficial epigastric veins are often dilated (indicative of portal obstruction), the patient probably has piles, and, in some cases, the hepatic facies is well marked. The patient is either of the thin and sallow type or is fat and flabby, the eyes have dark rims round them, the sclerotics are yellow, the complexion is of an earthy muddy type, and on the malar eminences and nose there may be enlarged and tortuous veins. The hepatic pain is persistent and pronounced, local spots of tenderness may be made out at the costal border, especially at the cartilages of the eighth or ninth ribs. Another painful spot may be found a few inches below the angle of the right scapula. The bowels are costive or irregular, the patient is mentally depressed, irritable, or even stupid, the tongue is usually much coated, the appetite is capricious, the patient being seldom capable of enjoying a good breakfast, but often able to indulge freely at other meals. Sleep is fitful and generally bad. Nausea is often complained of in the morning, piles are generally present—a 'fit of the piles' often giving temporary relief to the general symptoms. A permanently moist condition of, or an itching at, the anus is a very common complaint. Irregular slight rises of temperature may occur at night. The circulation is not good, and there may be chilliness or coldness of the legs. Headache, giddiness, and dyspeptic symptoms make up the clinical picture. The irritability of the patient is proverbial.

DIAGNOSIS.—The diagnosis is generally easy, the pain in the hepatic region, the enlargement of the liver, the intestinal disturbance, and the state of the tongue, generally sufficing to make it clear. In all cases attended with fever the possibility of an abscess of the liver must not be forgotten, and in some such cases time alone will clear the matter up. Pneumonia at the base of the right lung and pleurisy have been mistaken for acute hyperæmia and *vice versa*. Intercoastal neuralgia has been diagnosed in some cases of hepatic congestion, and inflammation of the gall-bladder has been mistaken for it. In perihepatitis there is usually some neighbouring organ affected, and in any case the pain in perihepatitis is usually very acute and localised. The fever at first is often looked upon as malarial, and treated as such. The possibility of abscess must ever be borne in mind, and careful inquiry made as to a previous history of former or recent dysentery.

The chronic form of congestion or 'tropical engorgement' is seldom mistaken for anything except gout, which may also be present. The early stages of malignant disease may be mistaken for mere congestion.

PROGNOSIS.—The prognosis of acute uncomplicated congestion is good. Out of 12,419 cases admitted into military hospitals in India only 42 died, a case mortality of only .3 per cent. The prognosis of acute attacks depends much on the patients themselves, and their ability to make the necessary changes in their habits of life; that of chronic congestion is not so good, since, though few

succumb to it directly, many go from bad to worse and die of some intercurrent disease or remain permanent invalids.

TREATMENT.—The lines both for prevention and treatment are indicated in the section on ætiology, viz. moderation in eating and drinking, and avoidance of chills. Regular exercise is essential, and for middle-aged men no game is better than golf, which can nearly always be had in the tropics. The public have a firm belief in a supposed necessity for violent exercise, to 'shake up the liver,' as they say, but an inflamed liver, like any other organ when inflamed, needs rest. A morning ride is excellent, but the same cannot be said for a violent game of polo followed by sedentary work in an office for the rest of the week.

For an *acute attack* rest in bed, abstention from alcohol, and light diet are essential; hot curried dishes and excessive tobacco-smoking are to be avoided. As regards drugs, the indication is to relieve the overloaded portal system by free saline purges. For this purpose Carlsbad Sprudel salts, Apenta, Hunyadi János, or other mineral waters are prescribed, to be taken in the early morning; the time-honoured blue-pill and colocynth at night is often invaluable. Formerly abstraction of blood by means of leeches was much in vogue, and was undoubtedly effective. Twenty grains of chloride of ammonium is still frequently prescribed. For *local treatment* the hepatic region may be painted over with the tincture of iodine, or a mustard-plaster may be applied, the latter often giving prompt relief. In *malarial hepatitis* treatment must be directed to the liver and spleen. The so-called 'spleen-mixtures' in India generally contain aperient salines with quinine and iron.

The chronic condition of tropical engorgement needs careful treatment. Rigid moderation above all is essential. The diet and daily supply of alcohol must be cut down with a rigid hand. For acute exacerbations the treatment must be as is indicated above for acute attacks. The 'hydropathic' belt should be worn for ten days or so, or till the skin gets red and raw. It can be made from a piece of swansdown cloth one foot broad, and long enough to go round the waist. It is applied round the waist over the hepatic region, covered with a piece of waterproof sheeting, and kept in its place by a broad bandage. Nitro-hydrochloric acid is often prescribed in these cases, but it is doubtful if it is of use in cases associated with intestinal catarrh. Attacks of diarrhoea are best treated by bicarbonate of sodium, and salol, or small doses of mercury and chalk. Bismuth and pepsin are useful, but astringents are generally harmful.

Patients suffering from tropical engorgement of the liver should be sent to Europe as soon as possible, and should undoubtedly undergo a course of treatment at Carlsbad. In the cold weather in India an artificial course of Carlsbad salts can be tried. A change to Kashmir will often be possible for those who cannot afford to get to Europe, or even the hill-stations in the dry weather may be tried. If the patient is a good sailor, a short sea-trip is an excellent change. If, however, the chronic engorgement is of long standing, every effort should be made by the patient to undergo the full course of treatment at Carlsbad.

W. J. BUCHANAN.

LIVER, Malformations of.—Abnormalities in the form of the liver are not common, and are

more often acquired than congenital. The following are some of the most frequently observed malformations that are *congenital*, and due to some original defect: A more or less quadrangular liver; a rounded liver; reduced proportions or total absence of left lobe; prolongation of the left lobe in the form of a narrow tongue-like process towards the region of the spleen; abnormal grooving of the surfaces of the liver; extreme depth of normal fissures. Another occasional variety of hepatic malformation consists in extensive lobulation, and the existence of one or more additional small lobes—a condition met with in the livers of rodent animals. *Acquired* malformation may be due to compression of the organ by tight-lacing, straps, and other means. In cases of hepatic malformation caused by tight-lacing, the upper part of the right lobe may be traversed from side to side, either by a single very deep furrow, or by two or more shallow depressions with elevated transverse folds of liver-tissue between them. In those instances in which the constriction has been so applied as to 'fold up' the liver, and to increase its convexity from before backwards, a single deep transverse furrow is often formed on the under surface of the right lobe. The hepatic tissue in the furrows atrophies; the fibrous tissue is often increased, especially just under the capsule.

A furrowed condition of the upper surface of the liver is often observed, in which elevated folds of hepatic structure, with corresponding depressions, take a direction from before backwards. This furrowing occurs in cases of obstructed respiration, and is held to be due to the pressure of the lower ribs on the liver, which organ is more or less fixed by depression of the diaphragm and by the strongly contracted abdominal muscles.

In 1888 Riedel directed attention to a partial malformation of the liver occasionally observed in association with cholelithiasis and a distended gall-bladder. In this condition the right lobe of the liver is extended downwards in the form of an attenuated tongue-shaped process (*floating lobe*).

W. JOHNSON SMITH.

LIVER, Malpositions of.—Abnormalities in the position of the liver are much less rare than abnormalities in its form. The more frequent forms of *congenital* displacement include—Lateral transposition, the liver being found on the left instead of the right side of the abdomen; eventration, the organ being exposed in front of the abdomen of a fetus; the presence of more or less of the liver in the chest, through congenital deficiency of the diaphragm. In *acquired* displacement the liver may be either depressed or elevated, some rotation of the organ on its transverse axis taking place in an opposite direction in each case. Depression may be caused by pressure from above, as by effusion in the right pleural cavity, and probably to some slight extent by considerable pericardial effusion, or cardiac hypertrophy. Elevation of the liver, which takes place more frequently, may be due to pregnancy, ascites, or the presence of some large abdominal tumour. Curvature of the spine, whether lateral or angular, usually gives rise to some change in the position of the liver. In Pott's disease the organ is often forced downwards towards the crest of the right ilium.

By tight lacing both the position and the form of the liver may be altered. The organ may be forced

downwards, and at the same time so twisted on its transverse axis that its convex surface looks directly forwards, and its concave surface directly backwards. See LIVER, Malformations of.

A liver quite free from structural disease may, under certain conditions of rare occurrence, be capable of considerable downward displacement within the abdominal cavity (*hepatoptosis*). This displacement of the liver is invariably associated with some deformity, the organ, according to Treves, being flattened out, 'so that the anterior surface is elongated at the expense of the superior surface, and the inferior surface at the expense of the posterior.' There is much difference of opinion as to the aetiology of this condition. It occurs in most instances in women who have had many children, or who have been weakened by much hard work, and is probably due to a relaxed state of the abdominal walls, associated with elongation of the suspensory ligaments of the liver. See ENTEROPTOSIS.

W. JOHNSON SMITH.

LIVER, Morbid Growths of.—Hydatid disease, cysts of various kinds, actinomycosis (p. 22), syphilitic gummata, angiomas, adenomata, and malignant disease in its various forms are each and all to be met with. Some of these are described under their own special headings; of the others, cavernous angioma need not detain us, as it has no clinical significance. It is found *post mortem* in the form of isolated patches of spongy naevoid tissue in the substance of the liver. Adenomata, in like manner, are small and rare, and might perhaps be better designated as an erratic localised lobular hypertrophy of the liver. They are of no practical importance.

Malignant Disease.—Cancerous or sarcomatous growths may occur in the liver either primarily or secondary to similar growths elsewhere.

ÆTIOLOGY.—Hepatic cancer is rare in early life. Habits of life or over-indulgence in the use of spirituous liquors do not seem to play any part in determining the malady. The influence of hereditary tendency to cancer must not, however, be overlooked, and it has been contended of late years that locality has an influence in bringing it about. Malignant disease of the liver and gall-bladder is primary in about one fourth of the cases; and in about one half of the remainder the primary disease is seated in structures connected with the portal system. Of such as *originate* in the liver, the disease in the larger number commences in the gall-bladder or the bile-ducts, and is of the nature of cylinder-celled cancer. Some few, at any rate, have appeared to be the direct outcome of the local irritation of a gall-stone.

ANATOMICAL CHARACTERS.—Malignant disease of the liver may be either carcinoma or sarcoma, the former being either hard or soft (scirrhous or medullary), the latter round-celled and occasionally melanotic. Colloid degeneration is rare. Cancer may occur as an infiltration of the liver-tissue, when large masses of the liver are uniformly affected, and little or no irregularity of surface results. It usually, however, occurs in circumscribed masses, smaller nodules or larger protuberances, varying in size, to use a familiar comparison, from that of a pea to that of a child's head. These masses are more or less numerous, and usually distinct; or they may encroach upon one another, and coalesce. When near the surface, they give rise to the marked irre-

gularity which is very characteristic of the disease ; and, when large and numerous, cause considerable increase in the size of the liver. The masses on the surface are sometimes flattened, and have a central depression (umbilication) which has been designated as 'cancer navel.' The cut surface is either white, or reddish-white, or darker red when blood has been recently extravasated, or of varying colour from altered blood-pigment, when the extravasation of blood has been of longer date. The portal and hepatic veins are sometimes invaded by the cancer.

SYMPTOMS.—In the earlier stage of this disease, the symptoms are indefinite. When far advanced, however, a prominent irregular swelling may be seen, raising the abdominal parietes, and occupying often a large portion of the abdominal cavity. Lesser grades of the disease may be detected by palpation and percussion. The liver will be found to extend more or less beyond its normal limits ; to be hard and resisting ; and, in a large proportion of cases, irregular. In a few cases, however, when the disease is of an infiltrating form, the surface will perhaps be smooth throughout. At times there is no enlargement of the organ, and the portion affected lies under the ribs, so that physical examination does not help us. There is often tenderness on pressure, especially when the peritoneal coat is inflamed. Usually, but not always, there is pain in the liver itself ; sometimes merely a feeling of tightness and fulness ; at other times a gnawing, aching pain ; and some patients have described the pain as 'burning.' There is frequently also pain shooting back to the spine, over the sacrum, or about the angle of the right scapula. A sensation as of a cord drawn round the right hypochondrium has been complained of. There is sometimes pain radiating down to the lower part of the abdomen ; and occasionally wandering pains in the extremities and body generally are complained of. When the stomach is intact, there may be no material disturbance of its functions, but usually derangement is manifested by loss of appetite, nausea, vomiting, and other symptoms, which will be intensified if the stomach is implicated in the disease. The bowels are, as a rule, constipated in the earlier stage, but toward the close there is often more or less looseness. Jaundice occurs in nearly one half of the cases of malignant disease of the liver, and is due to compression of the bile-ducts by cancerous masses within the organ, or by an enlarged lymphatic gland in the portal fissure. When once established it is permanent, and the colour of the patient varies, being pale yellow, or deep olive-yellow, or greenish, or sometimes of the dark hue which has given rise to the term 'black jaundice.' The stools in such cases are white or clayey in appearance ; and the urine deep-coloured from bile pigment. The condition of the urine, when there is no jaundice, is variable ; in the earlier stages of the disease it is generally scanty and pigmented, and loaded with urates ; in the last stage, copious, pale, and deficient in urea. This condition is due to the utter failure of digestive and nutritive power. Ascites is present in more than half of the cases, and is due either to compression of the portal vessels, or to implication of the peritoneum. Sometimes the large size of the tumour, especially if ascites be present, may cause much pressure upwards, and give rise to distressing chest-symptoms, such as embarrassed breathing or palpitation. Hæmorrhage not infrequently occurs

in advanced cases. The blood may come from the stomach or bowels, and be due to portal obstruction ; or may be of passive character, as in scurvy or purpura ; or the bleeding may take place beneath the skin. In the latter case the hæmorrhage is accompanied, according to Frerichs's experience, by intense jaundice, and usually by somnolence and delirium. The complexion of patients suffering from the disease under consideration, when there is no jaundice, is usually sallow, anæmic, earth-coloured. There is, in a large majority of cases, progressive and, towards the close, often extreme emaciation. Generally there is no fever, but it may be even considerable and of a hectic type, when the cancerous development goes on rapidly. When the disease of the liver is secondary to, and complicated with, cancerous affections of other organs, as the stomach—which occurs in a considerable proportion of cases—pancreas, uterus, or mammary gland, symptoms may exist indicating such complications, but need not be specially dealt with here.

DIAGNOSIS.—When hepatic cancer is somewhat advanced, and the liver large and irregular on its surface, the diagnosis will be easily effected. In the early stage, on the contrary, and throughout some cases in which the liver is not perceptibly enlarged, one must be cautious in giving a hasty or too decided opinion. Inherited tendency to cancer ; the age of the patient ; in women the period of 'change of life ;' a sallow earthy aspect ; progressive emaciation ; and pain in the right hypochondrium, point with fair probability to the disease. But nearly the same conditions and symptoms may be associated with aggravated hypochondriasis, or chronic catarrh of bile-ducts ; and in the latter case the difficulty of diagnosis is increased, as gall-stones are often present when there is cancer. Permanent closure of the bile-duct from other causes gives rise to persistent jaundice and other symptoms, as in the case of closure by pressure from a cancerous mass, but the emaciation and loss of strength are then seldom so rapid. Enlargement of the liver from malignant disease may be confounded with the following hepatic enlargements and malignant tumours : 1. Albuminoid or lardaceous disease. In this affection, the perfectly smooth surface, with preservation of normal shape of the liver, and absence of that peculiar hardness and pain in the tumour and of jaundice, will be sufficiently distinctive, accompanied as it should be by associated indications in other organs (*see* AMYLOID DISEASE). 2. In many cases of cirrhosis, as also of malignant disease, the liver is enlarged and its surface uneven, and in both diseases there is great resemblance in the aspect and general cachectic state of the patient, and similar disturbance of gastric and hepatic function. In cancer, however, the ascites is generally but slight, and the liver continues to increase, and is marked by large hard nodules and protuberances. In cancer the skin is often moist ; in cirrhosis it is harsh and dry. Intemperance is not an element in the ætiology of cancer, as it is in cirrhosis. In the latter disease, as also in lardaceous liver, the spleen is frequently enlarged. 3. Hydatid tumour is to be distinguished from a localised cancerous mass by the presence of more or less distinct fluctuation ; and the absence of pain, and of serious functional and constitutional symptoms. 4. A tumour caused by hepatic abscess might perhaps give evidence of fluctuation ; at any rate it would probably be associated with or

consecutive to dysentery; and is often attended by rigors, hectic fever, and characteristic shoulder-tip pain. 5. Malformations and malpositions of the liver have been mistaken for cancerous enlargement, especially in females about the period of 'change of life.' 6. A largely distended gall-bladder has been mistaken for a cancerous projection from the liver, but the smooth oval swelling, and the site of the enlargement, are for the most part distinctive. 7. Cancer of the omentum would present a movable tumour, separable, probably, from the liver by a slight area of tympanic resonance. 8. Cancerous deposits in the left lobe of the liver may be readily mistaken for cancerous affections of the stomach. The following points will assist in diagnosis: (a) Percussion even in cases of great thickening of the walls of the stomach gives a tolerably clear tympanic sound; in cancer of the left lobe of the liver, the sound is much more deadened, and is only somewhat tympanic on stronger percussion-stroke; (b) careful examination of the liver, and of the stomach, when full and when empty, will also lead to a correct conclusion; (c) even when the liver and stomach are both affected, careful examination may often make out the boundaries of disease in each. 9. Malignant tumour of the right lobe may be mistaken for enlargement of the right kidney; in the latter case percussion will generally reveal a tympanic zone between the hepatic dulness and the tumour, owing to the presence of intestine between the kidney and liver. The hepatic tumour is also distinguished from this and other abdominal tumours by its following the movements of the diaphragm in respiration. But when the renal enlargement is very great, diagnosis is not easy. 10. Malignant disease of the ascending or transverse colon will constitute a movable and generally somewhat tympanic swelling; and fecal accumulations in the colon may be removed, but not always readily, by aperients and injections. Percussion, too, will often elicit a resonant space between the enlarged intestine and the liver.

PROGNOSIS.—The prognosis is always unfavourable. Emaciation and loss of strength are usually progressive. The disease, when once fully pronounced, runs its course rapidly, the fatal termination being seldom deferred beyond a year. Scirrhus has usually a longer duration than medullary cancer.

TREATMENT.—This can be but palliative, and directed to rendering the inevitably fatal course as smooth as possible by relieving distressing symptoms. Remedies which in other hepatic affections are valuable, such as cholagogues, or mineral waters, are here useless, if not worse. The diet should be plain and nourishing; and the moderate use of wine and alcohol is not contra-indicated, as in other disorders of the liver. Serious gastric and other derangements must be met by appropriate remedies; it being always borne in mind that we have to soothe the patient, and not add to his distress by the exhibition of nauseous drugs. The administration of ox-gall is sometimes useful in the jaundice that is so common, and the liquor pancreaticus is also worth trial as an aid to the defective digestion of fats. For the relief of pain, the various preparations of opium are indicated, and, as a rule, morphine acts the best: it may be administered either internally, or by the hypodermic method, and must be repeated when pain demands it. Local applications over the liver, as poultices,

spongiopiline, &c., with tincture of opium sprinkled over the surface, are useful, especially when the peritoneal coat is inflamed. Tapping should not be had recourse to for the relief of ascites, unless this becomes so great as to interfere by upward pressure with the functions of the lungs or heart. The fluid soon re-accumulates, and the effect of the operation is to hasten the fatal termination.

JAMES F. GOODHART.

LIVER, Nutmeg.—SYNON.: Fr. *Foie Noix de Muscade*; Ger. *Muskatnussleber*.—See LIVER, Hyperemia of, Passive.

LIVER, Syphilis of.—A. **Hereditary Syphilis.**—SYNON.: Congenital syphilis; Pericellular, monocellular, intercellular cirrhosis.—In infants affected with hereditary syphilis the liver is much more often affected than in the acquired disease; this is in favour of the view that the poison arrives from the placenta by the umbilical vein, which it will be remembered supplies blood to the liver, rather than that the ovum is directly infected by a syphilitic spermatozoon.

MORBID ANATOMY.—To the naked eye in the slighter cases the liver is little, if at all, altered; in more marked instances it may be brown, yellow, or even of a violet hue. It is enlarged, and may show adhesions on the surface. On section it is tougher than in health, and marbled, with loss of the normal lobulation. Small miliary spots, minute granulomata, are generally visible; in exceptional instances genuine gummata or localised areas of fibrosis have been present. Histologically the change is that characteristic of secondary syphilis, a diffuse small-celled infiltration between the liver-cells, and contrasts with the localised lesions of tertiary syphilis. This intercellular small-cell infiltration is accompanied by degenerative changes in the hepatic cells, and may develop into varying degrees of fibrous tissue. The small spots resembling miliary tubercles are collections of small round cells (syphilomata). Very considerable variations may occur in the lesions actually found in congenital hepatic syphilis; Hudela described as many as seven different types.

CLINICAL FEATURES.—Enlargement of the liver and spleen in a child with other evidences of hereditary syphilis justifies the diagnosis. The liver is smooth, firm, and tender, while its size is a rough indication of the severity of the disease. Very exceptionally a definite tumour can be felt. Jaundice and ascites are rare.

TERMINATIONS.—When death occurs in infants with congenital syphilitic disease of the liver, it is due to marasmus and not to the direct effects of the hepatic lesion. Inasmuch as it is a secondary lesion, intercellular cirrhosis is curable and reacts well to mercury, and in most cases that survive the liver probably recovers completely. As a late result of untreated hereditary hepatic syphilis tertiary manifestations may develop. This *delayed hereditary syphilitic* disease shows itself about puberty or even later. The liver may be much scarred by cicatrices and deformed by gummata, while extensive lardaceous disease may in addition be present. In other words, it is the same as the tertiary lesions of acquired syphilis. It is probable that, as a result of intercellular cirrhosis that has undergone resolution, the liver is left in a condition of more or less lowered resistance. If the causes of ordinary portal cirrhosis then arise, the liver falls a more ready prey, and what may be called *parasyphilitic cirrhosis*

results. Multilobular cirrhosis in children, formerly the subjects of intercellular cirrhosis, is thus analogous to the parasymphilitic lesions of acquired syphilis, tabes dorsalis, and general paralysis of the insane. Probably many of the cases of multilobular cirrhosis in young children are of this nature.

TREATMENT.—This is that of hereditary syphilis, i.e. mercury either by inunction or by the mouth. Mercurial ointment should be rubbed into the skin of the axilla or groin daily for the first three months, then it should be intermitted for a week, and later for two weeks at a time, and should be continued into the second year when it should be practised for one month in every three. Mercurial inunction may be carried out by placing the ointment under the child's binder and letting it work in, but this is less satisfactory than the first-named method. Inunction is more effective than giving hydrargyrum c. cretâ by the mouth, since the latter may set up diarrhoea. To a child under two months of age half a grain should be given twice a day and the dose gradually increased. The treatment of delayed or tardive hereditary syphilis is that of tertiary syphilitic disease of the liver, while that of parasymphilitic cirrhosis is the same as in portal cirrhosis.

B. Acquired Syphilis.—*In the secondary stage* jaundice is sometimes seen synchronously with the roseola; it yields to mercury and not to the ordinary remedies for catarrhal jaundice, and is therefore probably directly related to syphilitic infection. It has been referred to various causes, such as a change in the mucous membrane of the ducts analogous to that of the cutaneous roseola, to pressure exerted by enlarged glands in the portal fissure, or to a general toxic change in the liver-substance leading to catarrhal changes in the minute bile-ducts. The jaundice is benign and must be distinguished from that of acute yellow atrophy which in some rare instances has been known to attack the subjects of secondary syphilis. It appears that women are more disposed to this benign syphilitic jaundice than men.

Intercellular cirrhosis has generally been considered to be pathognomonic of hereditary syphilis, but it seems almost certain that it also occurs in the secondary stage of the acquired disease, though opportunities for investigation of this point are infrequent.

In the tertiary stage the liver may show gummata and cicatrices, while lardaceous disease is a well-recognised sequela of syphilis. Syphilitic change in the liver is much commoner than in any other internal organ, but it is not nearly so frequent as in hereditary syphilis. Men are more often affected than women, and it has been thought that local factors such as traumatism, alcoholism, or past affections of the liver such as jaundice may determine syphilitic lesions. Gummata are usually multiple, and are commoner in the larger right lobe and on the anterior surface. They are not uncommon near the falciform ligament, and may set up local perihepatitis or adhesions to the diaphragm. By contraction of cicatrices and gummata the liver may become lobulated, deformed, and extensively scarred; and parts of the organ may be practically destroyed. Usually the lesions are localised and the intervening liver-tissue is fairly healthy, but the organ may be widely lardaceous or there may be localised lardaceous change around a gumma. On section a gumma has a dead-white appearance and is dry and slightly friable. Cicatrices depress the surface of

the liver and invade it for a short distance. Gummatous change may give rise to very considerable enlargement of the liver, especially when combined with lardaceous change.

In its earliest stage a gumma is a mass of pink granulation-tissue; as the result of impaired vitality the central part dies and from fatty degeneration becomes caseous. Around the caseous centre giant-cells are seen, while further out the granulation-tissue organises into a fibrous capsule; the arteries in this area show endarteritis obliterans. This fibrous capsule invades the adjacent lobules, which are, moreover, occupied by a small-cell infiltration. In young gummata the fibrous capsule is but slightly developed, while in old ones the capsule is thick, contracts, and may contain calcareous material. As a result of contraction and absorption a gumma may shrivel into a cicatrix perhaps containing a central core of caseous material. Cicatrices may be the relics of gummata, or may arise from organisation of syphilitic granulation-tissue without any preliminary caseation. Now that prolonged suppuration is less common, syphilis is the more frequent cause of lardaceous disease of the liver. See AMYLOID DISEASE.

CLINICAL FEATURES.—Gummata and especially cicatrices not uncommonly are quite latent and give rise to no symptoms. The clinical manifestations may be postponed for many years after the primary infections, though a fair proportion of cases give rise to trouble within three years of infection. Very considerable variation exists in the clinical picture produced by syphilitic disease of the liver. In many cases portal cirrhosis or chronic peritonitis is imitated; probably many reputed cures of cirrhosis with ascites are of this nature. Hæmatemesis is rare and digestion is much less disturbed than in cirrhosis; the subcutaneous abdominal veins may be enlarged; and pain, tenderness, and uneasiness in the right hypochondrium may depend on syphilitic inflammation of the capsule of the liver. In other instances gummatous disease of the liver simulates malignant disease; a definite tumour or tumours in an enlarged liver are found, and may be associated with ascites or less commonly with jaundice. In the absence of ascites and other signs, a large gumma may resemble a deeply seated hydatid cyst. In rare instances a large gumma is associated with fever, and may then suggest intrahepatic suppuration, malaria, or even tuberculosis or typhoid fever. Exceptionally a gumma involving the bile-ducts in the portal fissure closely simulates gall-stones; the diagnosis is very difficult, and in the absence of any evidence of syphilis impossible. When gummata are combined with lardaceous disease their presence may be easily overlooked.

The *diagnosis* depends on evidence of past syphilis or on the relief of the symptoms after antisymphilitic treatment. Even in the entire absence of any proof of syphilis, antisymphilitic treatment should always be tried in cases suggesting portal cirrhosis or chronic peritonitis, and in hepatic tumours of doubtful origin; and in some of these improvement will decide the diagnosis. It must be remembered that cicatrices cannot be removed by treatment, and that the failure of antisymphilitic treatment does not necessarily and absolutely disprove syphilis. The *prognosis* of syphilitic disease of the liver is, when treated, fairly good and far more hopeful than in the conditions—cirrhosis, chronic peritonitis, malignant disease—that may imitate it.

TREATMENT should consist in adequate doses of iodides combined with mercury. The iodides of potassium, sodium, and ammonium should be given at first so that 20 grains of iodide salts are taken in the twenty-four hours; this should be increased until 80 or 90 grains are taken in the twenty-four hours. Mercury may be given in the form of hydrargyrum c. cretâ combined with powdered opium to prevent diarrhœa, or the liquor hydrargyri perchloridi may be combined with the iodides. When gummata develop rapidly and early after infection, intra-muscular injections of soluble mercurial salts may be employed. Recently large gummata have been partially removed with good results in promoting absorption under medical treatment.

H. D. ROLLESTON.

LIVER, Tubercular Disease of.—Tuberculosis may affect the liver (1) as part of a general acute infection (*acute miliary tuberculosis*); (2) as a local disease spreading from, and limited to the neighbourhood of, the bile-ducts (*tubercular cholangitis*); and (3) as single limited foci of 'conglomerate tubercle.' Only the second variety has any clinical interest. It may give rise to attacks resembling biliary colic without jaundice. It does not cause ascites, and rarely produces any local symptoms or signs.

LIVER-FLUKE.—A common name for the *fasciola*. See ENTOZOA.

LLANDRINDOD, in Radnorshire, South Wales.—Saline, sulphated, and chalybeate waters. See MINERAL WATERS.

LOBULAR (*lobulus*, a little lobe).—Of or belonging to a lobule. A term generally applied to morbid conditions affecting individual lobules of organs which are thus constituted, such as *lobular pneumonia*, *lobular pulmonary collapse*, and *lobular hepatitis*.

LOCK-JAW.—A popular synonym for tetanus. See TETANUS.

LOCOMOTOR ATAXY (*locus*, a place; and *κινεω*, I move; *ἀ*, priv., and *τάξις*, order).—See TABES DORSALIS.

LOECHE-LES-BAINS (LEUKERBAD), in Switzerland.—Thermal calcic waters and climatic health resort. See MINERAL WATERS.

LORDOSIS (*λорδός*, bent).—A term applied to abnormal curvature of the spine forwards. It is found chiefly in the lumbar region as an increase of the natural curvature; but it may also occur in the dorsal and cervical regions. See SPINE, Diseases of.

LORETO, in the Romagna in Italy.—Saline waters. See MINERAL WATERS.

LOS ANGELES, the capital of southern California. A health-resort, 110 miles from the Pacific coast, in a well-sheltered fertile valley at an elevation of 371 feet. Famous for its orange and lemon groves. Pasadena, a suburb, lies 500 feet higher, and is well supplied with hotel accommodation. Climate mild, but not marked by the degree of equability of temperature that characterises the Pacific stations. Mean temperature 61° F.; mean daily range 24° F.; and rainfall 15 inches.

LUCCA, in Tuscany.—Thermal waters containing sulphate of calcium with iron. See MINERAL WATERS.

LUCID INTERVALS.—No better definition of this state has been given than that of Lord Thurlow, who calls it 'an interval in which the mind, having thrown off the disease, had recovered its general habit.' It must be regarded as extremely unlikely that a perfect restoration to reason has taken place in the course of any long-continued insanity, without full opportunity having been afforded of testing its nature. The law more readily recognises the restoration of the mind to a state of civil capacity such as will render testamentary acts valid, than such temporary recovery as would restore responsibility for crime. If a civil act be rationally performed, the law accepts that as *prima facie* proof of the capacity of the agent; but juries very seldom convict the accused of a crime if insanity is proved to have existed within a short period of its commission. JOHN SIBBALD.

LUHATSCHOWITZ, in Moravia.—Muriated alkaline waters. See MINERAL WATERS.

LUMBAGO (*lumbi*, the loins).—SYNON.: Fr. *Lumbago*; Ger. *Lendenweh*.—Muscular rheumatism affecting the muscles and fasciæ of the lumbar region. See RHEUMATISM, MUSCULAR.

LUMBAR ABSCESS.—An abscess, generally of spinal origin, occupying the lumbar region, or pointing in the loin external to the erector spinæ. See PSOAS ABSCESS.

LUMBAR ANÆSTHESIA.—Professor Bier at Kiel and Monsieur Tuffier in Paris have lately performed many operations under the local analgesia produced by injecting 1-4 centigrams of a freshly prepared and sterilised solution of 1 in 200 hydrochlorate of cocaine into the lumbar subarachnoid space. The method has not been adopted, to any great extent, in England; but it may possibly prove useful when the operator is single-handed, especially in extraperitoneal and thoracic operations. Vomiting occurs so often during the period of analgesia that it is not adapted for the more serious intraperitoneal operations. See ANÆSTHESIA, LOCAL. D'ARCY POWER.

LUMBAR PUNCTURE.—DESCRIPTION.—The operation of puncture of the spinal canal in cases of meningitis may be employed in adults, but is usually performed in children. It consists in withdrawing the cerebro-spinal fluid from the subarachnoid space which is punctured between the laminae of the third and fourth lumbar vertebrae. A fine trocar and cannula are well boiled, and the skin of the patient is rendered sterile. The child is then placed upon its right side with the thighs so bent that it is curled up and the vertebral column is well bowed. The spine of the fourth lumbar vertebra is then found either by counting downwards from the last dorsal vertebra, to which the twelfth rib is attached, or by dropping a perpendicular upon the bed from the highest point of the crest of the ilium, since this line crosses the upper border of the spine of the fourth lumbar vertebra. This point is selected because in a child at birth the spinal cord only reaches as low as the third lumbar vertebra, while in an adult the lower limit of the cord is level with the lower border of the first lumbar vertebra. The

exact point of puncture may be marked with a drop of iodine, and local anæsthesia may be produced by ethyl chloride, but this is not often necessary. The trocar and cannula are plunged through the skin immediately to one side of the spine of the third lumbar vertebra and on a level with its lower border. It is pushed on boldly until the point of the trocar strikes the bone—the lower border of the lamina. The handle of the trocar is then directed upwards so that its point passes downwards over the lamina, and it is pushed onwards until a grating sensation is felt, caused by the trocar passing through the ligamentum subflavum. The trocar is withdrawn as soon as the cannula has fairly entered the subarachnoid space, and the cerebro-spinal fluid issues either in a stream or drop by drop. The quantity of fluid which escapes varies greatly: it is often only a few drops, but the average amount is from 4 to 12 drachms. It flows more rapidly when the patient is raised than when he is recumbent, and the rate often varies synchronously with the respiratory rhythm. The cannula is withdrawn as soon as sufficient fluid has been collected, the puncture is sealed with a film of cotton-wool soaked in collodion, and a pad and bandage are applied. The operation is trivial, and the writer has never seen any harm result from it, though clumsy operators have broken their needles against the laminæ, and a few cases of death within 24 hours of the puncture have been recorded. The surgeon at first is a little apt to under-estimate the thickness of the erector spinæ, and his needle thus fails to penetrate the canal; his labour is then in vain, and no fluid escapes.

USES.—Lumbar puncture is more or less useful for diagnostic purposes in cases of meningeal hæmorrhage, hydrocephalus, acute serous, sero-fibrinous, purulent, and tubercular meningitis, but it does not seem to have any remedial or curative value. The cerebro-spinal fluid obtained by lumbar puncture in these affections, as well as in the obscure nervous disorders secondary to infective diseases in children, which are now grouped together provisionally under the term 'meningism,' should always be examined histologically, by inoculation into animals, and by plate-cultivation. Reliance should never be placed upon a single method or upon one inoculation.

D'ARCY POWER.

LUMBRICUS.—By many practitioners this term is still employed to designate the large round worm (*Ascaris lumbricoides*). The title is entirely a misnomer, for, notwithstanding its general resemblance to ordinary earth-worms, its organisation is totally different. Occasionally, in practice, patients seek to deceive the medical attendant, by placing one or more earth-worms in the night-stool or chamber-pot. See ENTOZOA.

LUNACY, Law of.—Medical men and lawyers look at insanity from somewhat different points of view. A medical man applies his mind to its study so as to ascertain how far he may infer from the evidences of mental action the existence of morbid conditions which he may hope to alleviate or remove. It is therefore his duty to be acquainted with such symptoms as give the earliest indication of the approach or development of these morbid processes. For it is during their initial stages that he may most successfully intervene with the resources of his art, to check their progress or to ward them off. He therefore identifies with the existence of disease every deviation from the healthy

mental standard which indicates the necessity for medical treatment or advice. A lawyer, on the other hand, takes note of insanity only in so far as it affects the safety of person or the preservation of property. The question which he seeks to determine is whether a person is justly responsible for certain acts which he has committed, or is competent to perform certain acts which he may be called upon to perform. It is evident, therefore, that the legal view of insanity must naturally be much more limited than the medical. 'A lawyer, when speaking of insanity,' says Sir James Stephen, 'means conduct of a certain character; a physician means a certain disease, one of the effects of which is to produce such conduct;' and though this has been adversely criticised, it seems to show correctly the directions in which the two views diverge. They might perhaps be as fairly indicated in other words if we say that the lawyer has to deal with the nature or quality of certain acts, while the physician has to deal with the condition of certain persons. No satisfactory general definition of legal insanity which would suit all cases ever has been given, or ever can be given. In the earlier ages of our legal system none but the most violent or degraded cases of insanity were recognised. Bracton in the thirteenth century defined a madman as 'one who does not understand what he is doing, and, wanting mind and reason, differs little from brutes.' Sir Edward Coke, though he recognises different classes, according as the insanity is congenital, permanent, or temporary, only admits that a person is insane when he is *non compos mentis*, or has wholly lost his memory and understanding. Sir Matthew Hale, in the seventeenth century, was the first to recognise the existence of less extreme forms of insanity. 'Some persons,' he said, 'that have a competent use of reason in respect of some subjects, are yet under a *particular dementia* in respect of some particular discourses, subjects, or applications; or else it is partial in respect of degrees, and does not excuse persons who commit capital acts in this state.' He also said that it is 'very difficult to define the invisible line that divides perfect and partial insanity,' and 'that most persons that are felons of themselves or others, are under a degree of partial insanity when they commit these offences.' The recognition of these gradations reaching even to the mutual overlapping of crime and insanity, indicates as much breadth of view as could be expected at a time when the very judge who recognised them passed sentence of death on persons convicted of witchcraft. We cannot doubt, indeed, that at that period the ignorance of the nature of insanity was such that many lunatics were executed for this offence. The recognition of the necessity of taking legal account of degrees of insanity less severe than 'furious madness' or idiocy may be said to have commenced at the beginning of the nineteenth-century. The medical practitioner requires to be acquainted with the present legal relations of insanity chiefly from three points of view: 1. Where a person suffers from such unsoundness of mind that it is necessary for his welfare, or the safety of the public, that his liberty should be restricted by his being placed in an asylum or subjected to similar restraint. 2. Where a person suffers from such unsoundness of mind that he is incapable of managing himself or his affairs. 3. Where irresponsibility for crime, on account of insanity, is pleaded in a

court of law. The subject is only dealt with in this article from the first of these points of view. The other two aspects of the subject are treated in the articles on CIVIL INCAPACITY, and CRIME, Irresponsibility for.

The lunacy statutes differ slightly in the three divisions of the kingdom. It will therefore be necessary, after describing what is required under the law in England, to show where its requirements differ from those which exist in Scotland and Ireland. The details to be given here will only include what is necessary for the information of the general practitioner. Any one who intends to devote himself specially to the treatment of the insane, or to receive one or more persons of unsound mind into his house, will find the regulations with which he must comply fully described in works specially devoted to the subject. When a person living in his own home is under treatment for insanity, the medical attendant is justified by the common law in adopting any measures of restraint which may be necessary for safety or the proper treatment of the malady. This has been decided by the courts of law in recent cases. If, however, it is proposed to place the patient in an asylum, or under the charge of any person who is to derive profit either directly or indirectly from the proceeding, it is necessary that certain forms should be carefully observed.

In the case of a *Chancery lunatic*, the patient may be taken charge of by his 'Committee of the Person,' or he may be received into an asylum or other institution for lunatics, or into a private house, on an order by the committee. Such an order must, however, have annexed to it an official copy of the appointment of the committee. If no committee has been appointed, an order by a Master in Lunacy is sufficient authority for the detention of the lunatic.

In the case of *other private patients*, it is necessary, under the Lunacy Acts of 1890 and 1891, to have a *reception order* made by the 'judicial authority.' The judicial authority under the Act is either a judge of county courts, a stipendiary magistrate, a metropolitan police magistrate, or a Justice of the Peace or chairman of a board of guardians duly and specially appointed for such duty. This order is obtained by private application upon a *petition*, accompanied by a *statement of particulars* and by two medical *certificates*. These must be made in the forms prescribed by statute.*

THE PETITION.—This document must be signed, if possible, by the husband or wife, or by a relative, and, if not, it must contain the reasons for its being signed by another person, and a statement of the connection of that person with the patient. The person signing the petition must be at least twenty-one years of age, and must have seen the patient within fourteen days of the date of presenting the petition. If a petition for a Reception Order has been previously presented in regard to the patient, and has been dismissed, the facts relating thereto must be stated in the petition; and there must be presented along with it a copy, to be obtained from the Commissioners in Lunacy, of the statement received by the Commissioners of the reasons for such dismissal. If one of the medical certificates

is not given by the usual medical attendant on the patient, the reason for this must be stated in the petition; and if an urgency order (hereafter described) has been made in regard to the patient, it must be referred to in the petition. No member of the managing committee of a hospital can sign the petition for the reception of a patient into that hospital.

THE MEDICAL CERTIFICATES.—One of the medical certificates must, whenever practicable, be by the usual medical attendant on the patient. Each certificate must be on a separate sheet of paper, and each person who signs a certificate must have separately examined the patient not more than seven clear days before the presentation of the petition, and must be a person registered under the Medical Act, 1858, and in actual practice. Certain persons are disqualified for signing either of these certificates or the certificate required in support of an urgency order. These are: The petitioner, or the person signing the urgency order, or the husband or wife, father or father-in-law, mother or mother-in-law, son or son-in-law, daughter or daughter-in-law, brother or brother-in-law, sister or sister-in-law, partner, or assistant of such petitioner or person. The statute also forbids the following persons from signing certificates: The manager of the institution into which the patient is to be received; the person who is to have charge of the patient as a single patient; any person interested in the payments on account of the patient; any regular medical attendant in the institution; or the husband or wife, father or father-in-law, mother or mother-in-law, son or son-in-law, daughter or daughter-in-law, brother or brother-in-law, sister or sister-in-law, or the partner or assistant of any of these persons. Again, neither of the persons signing the certificates can be the father or father-in-law, mother or mother-in-law, son or son-in-law, daughter or daughter-in-law, brother or brother-in-law, sister or sister-in-law, or the partner or assistant of the other of them. And no member of the managing committee of a hospital can sign a certificate in the case of a patient to be received into that hospital.

THE RECEPTION ORDER.—The judicial authority may, upon the presentation of the petition and certificates, make the reception order forthwith; or, if the certificates are not regarded as satisfactory, or for any other reason, he may appoint a time, not more than seven days after the presentation of the petition, for its consideration, and may, if he thinks necessary, visit the patient. The petition is then considered in private, and no one except the petitioner, the alleged lunatic (unless the judicial authority otherwise order), any one appointed by the alleged lunatic for that purpose, and the persons signing the medical certificates—all of whom are bound to keep secret the matters disclosed—can, without leave of the judicial authority, be present. A further adjournment for not more than fourteen days may then be made for further inquiry if the judicial authority shall think fit, after which he either grants the order or dismisses the petition. A reception order is sufficient authority for the person signing the petition, or some one authorised by him, to take the patient and convey him to the place mentioned in the order; but it does not continue in force unless the patient is received in the asylum or house within seven days of its date, except when the execution of the order

* These forms can be obtained at any law stationer's; but, as they are frequently wanted with the least possible delay, we mention the name of Messrs. Shaw & Sons, 6 Fetter Lane, London, E.C., as in the habit of supplying them.

has been suspended by reason of a medical certificate that the lunatic is not in a fit state for removal—in which case the order continues in force for fourteen days, unless a subsequent certificate is given that the patient is fit for removal, and in that case the order remains in force only for three days after the date of that certificate.

THE URGENCY ORDER.—If the necessity for placing a patient in an asylum or house is regarded as urgent, an order, called an 'urgency order,' may be signed as in the case of the petition by a husband or wife, or by a relative; and, if signed by another person, the reason for this must be stated, and also the connection of that person with the patient. The person signing must be at least twenty-one years of age, and must have seen the patient within two days of the date of the order. This order must be accompanied by a statement of particulars similar to the statement of particulars which is required to accompany the petition, and by a medical certificate stating that it is expedient for the welfare of the patient, or for the public safety, that the patient should be forthwith placed under care and treatment. The certifier in this case must have seen the patient not more than two days before his reception. An urgency order is sufficient authority for a person, authorised by the persons making the order, taking the patient and conveying him to the place mentioned in the order, and it remains in force for his detention for seven days from the date of the order; or, if a petition has been presented, it remains in force till the petition has been disposed of. An urgency order may be made either before or after a petition has been presented; but, if made before, it must be referred to in the petition, and, if made after, a copy of it must be sent forthwith to the judicial authority to whom the petition has been presented.

The information contained in the foregoing paragraphs indicates sufficiently for the purposes of the general practitioner the steps which require to be taken for placing a person of unsound mind under care and treatment. It is of the greatest importance, however, in filling up the several forms, that the most scrupulous attention should be given to the marginal notes which are attached to the forms. Great care must be taken to ensure that the instructions contained in these marginal notes are complied with in every, even the smallest, detail. For it may happen that what may appear to many to be a trifling deviation from the instructions, will render the document invalid, and thus entail much inconvenience and distress. In regard to the medical certificates, it should be kept in view that the persons who sign them must arrive at opinions in regard to two questions which are quite distinct. Each certifier has first to determine whether the patient is of unsound mind, and, next, whether it would be proper to place him under detention. In stating the facts, it must be borne in mind that they must be such as will appear to the judicial authority making the reception order sufficient evidence of insanity. Great care must be taken to state the facts both intelligently and accurately. There must be sufficient in the facts observed by the medical man himself to justify the opinion to which he certifies. A certificate founded solely on information obtained from others is invalid, and such information should be regarded by the certifier as useful merely to corroborate his opinion. It must also be kept in view that the opinion must be

directly deducible from examination of the patient on the particular day and at the particular place specified. The statement of facts observed should therefore contain at least one statement of a fact, or combination of facts, which could not be made in regard to a person of sound mind. A frequent error is the stating of the facts in such an imperfect manner that, though they may have been as a matter of fact sufficient evidence of insanity, the manner in which they are recorded makes them appear to be insufficient. It is sometimes stated, for example, that a patient 'believes himself to be possessed of great wealth'—without adding that this is an erroneous belief. Another kind of failure to state the facts intelligently is illustrated by an actual instance where they were given thus: 'His appearance, manner, mode of speaking, as well as his conduct.' These were probably quite adequate to prove to the certifier that the patient was insane, but it is obvious that they afforded no proof to those who merely read the statement.

If a lunatic, who is not a pauper, and not wandering at large, is not under proper care and control, or is cruelly treated or neglected by any relative or other person having the care or charge of him, information should be given to a constable of the district or a relieving officer or overseer of the parish, who is bound within three days to take steps, prescribed by statute, to have him placed in an institution for lunatics.

The duties performed by medical men and others in connection with the placing of patients under care and treatment have been frequently the source of great trouble and expense, from legal proceedings taken against them by patients or others who have felt themselves aggrieved. In order to afford protection against such action, when improperly taken, it is provided in the Lunacy Act of 1890 that a petitioner or certifier 'shall not be liable to any civil or criminal proceedings, whether on the ground of want of jurisdiction or on any other ground, if such person has acted in good faith and with reasonable care.' If such proceedings are taken, they 'may, upon summary application to the High Court of Justice or a judge thereof, be stayed upon such terms as to costs and otherwise as the court or judge may think fit, if the court or judge is satisfied that there is no reasonable ground for alleging want of good faith or reasonable care.' Even under the protection afforded by this enactment, it will be understood that both expense and trouble may be occasioned by vexatious proceedings, as the steps necessary to get proceedings stayed by the High Court may involve considerable outlay.

Any one who makes a wilful misstatement of any material fact in any petition, statement of particulars, or medical certificate, is guilty of a misdemeanour; but no prosecution for such misdemeanour can take place except by order of the Commissioners in Lunacy, or by the direction of the Attorney-General or the Director of Public Prosecutions.

A private patient may be discharged from the asylum or house in which he has been detained on the written authority of the person on whose petition the reception order was made, or, if this person is dead or incapable, by the person who made the last payment on account of the patient, or by the husband, or wife, or next-of-kin. If a patient should die while under detention, it is necessary to

give notice of the death to the coroner and to the Commissioners in Lunacy.

In the case of *pauper lunatics*, the procedure is somewhat different from that required for private patients. Any one aware of the existence of an insane pauper in a parish ought, if the case is a proper one for treatment in an institution for lunatics, to give notice to the relieving officer or the overseer. When a district medical officer under the poor-law becomes aware of such a circumstance, it becomes his statutory duty to give this notice in writing within three days after obtaining such knowledge. The relieving officer or overseer may then take steps to have the patient placed in an institution for lunatics upon one medical certificate, accompanied by the order of a justice of the peace, if the justice is satisfied that the alleged pauper is either in receipt of relief, or in such circumstances as to require relief for his proper care.

In order to place either a private or a pauper patient in an asylum in *Scotland*, a petition, accompanied by a statement and two medical certificates, has to be presented to the sheriff.* In the case of a private patient, the person signing the petition must state the degree of kinship or other relation in which he stands to the patient. In the case of a pauper, the petition must be signed by the inspector of the poor. In either case, if there be reasonable ground for so doing, the patient may be placed in the asylum on what is called a 'certificate of emergency,' signed by one medical man. If, however, the order of the sheriff is not obtained within three days thereafter, the patient must be discharged. In the case of a patient placed for profit in a private dwelling-house in *Scotland*, the fact must be reported to the General Board of Lunacy for *Scotland*, and the sanction of the Board obtained.

The procedure required for placing a patient in an asylum in *Ireland* resembles that which is required in *England*. For admission to a private asylum, an order and two medical certificates must be filled up and signed, subject to regulations resembling those already described as enforced in *England*; but the facts indicating insanity do not require to be stated in the certificates.* Pauper patients are placed in district asylums, and are admitted to these institutions on application being made at the asylum of the district in which the patient resides. The necessary form is obtained at the asylum. It consists of (1) a declaration to be made before a magistrate that the patient is insane and destitute, and has no friend able or willing to pay for his board in an asylum; and to this is annexed a statement descriptive of the patient; (2) a certificate by a magistrate, and a clergyman or poor-law guardian, in corroboration of the declaration; and (3) a medical certificate of insanity. When these forms have been filled up, it is necessary to wait until it is notified to some of the friends of the lunatic that there is room for him at the asylum. The procedure specially designed for the committal of dangerous lunatics is, however, frequently adopted in placing paupers in asylums; but this is a course which ought to be avoided, and which the medical practitioner ought specially to discourage. According to this procedure, the patient requires to be apprehended by the police, and brought

before two Justices of the Peace. These call to their aid the medical officer of the dispensary district, and either discharge the patient or order his removal to the asylum. Patients who are not destitute, but whose friends are unable to pay the rates of board charged in private asylums, are received into district asylums at low rates, upon application being made at the asylum in a similar manner to that already described for paupers. The chief difference between the two forms is that, in the case of patients not destitute, the medical certificate requires to be signed by two medical men instead of only by one.

JOHN SIBBALD.

LUNATIC (*luna*, the moon).—SYNON.: *Fr. Lunatique*; *Ger. Mondsüchtig*.—A designation given to persons suffering from mental disorder, because such subjects were formerly believed to be peculiarly affected by lunar influences. The term is used popularly as synonymous with 'insane.' In medical literature it is seldom employed, but the legal relations of the word are important. The adjective 'lunatic' is also used to signify that the object with which it is associated is connected with insanity, as *lunatic asylum*. See *INSANITY*.

LUNGS, Diseases of.—The diseases of the lungs will be dealt with in the following order:

Abscess, p. 908.
Active Hyperæmia, p. 908.
Amyloid Disease, p. 909.
Apoplexy, p. 909.
Atrophy, p. 909.
Brown Induration, p. 909.
Cancer, p. 909.
Cirrhosis, p. 909.
Collapse, p. 909.
Compression, p. 910.
Congestion, p. 911.
Consumption, p. 911.
Embolism, p. 911.
Empysema, p. 911.
Gangrene, p. 914.
Hæmorrhage, p. 915.
Hydatids, p. 916.
Hyperæmia, Passive, p. 917.
Hypertrophy, p. 918.
Induration, p. 918.
Infarction, p. 918.
Infiltrations, p. 918.
Inflammation, p. 918.
Inflation, p. 935.
Malformations, p. 935.
Malpositions, p. 935.
Morbid Growths, p. 935.
Oedema, p. 935.
Perforation, p. 936.
Rupture, p. 938.
Syphilitic Disease, p. 938.

The following articles appear in their alphabetical order in other parts of the Dictionary: ACTINOMYCOSIS; CAVITY; CHEST, Deformities of; CHEST-WALLS, Morbid conditions of; COUGH; EXPECTORANTS; HÆMORRHAGE (including Hæmoptysis); MEDIASTINUM, Diseases of; PAIN IN VISCERAL DISEASE; PHTHISIS; PHYSICAL EXAMINATION; PLEURA, Diseases of; PNEUMOCONIOSES; PULMONARY VESSELS, Diseases of; RESPIRATION, Disorders of; SPIROMETER; SPUTUM; STETHOGRAPH; STETHOMETER; STETHOSCOPE; TUBERCULOSIS.

LUNGS, Abscess of.—**DEFINITION.** Circumscribed suppurative of the pulmonary tissue.

ÆTIOLOGY.—Pulmonary suppuration occurs in many different conditions. These will be considered under the following headings: (1) A pneumonic lobe may disintegrate and become riddled with innumerable small pus-containing cavities large enough to give rise to suggestive physical signs, and yielding a characteristic expectoration; or the lobe may become gangrenous or break down at one or more spots into definite abscesses. (2) Pulmonary tuberculosis may in the same way result in one part of the lung becoming riddled with similar cavities; or a large cavity or a circumscribed cavity of limited size may be formed. The last not infrequently occurs at the base of the lung. (3) Chronic non-tubercular cavities are met with in various situations, the causation of which is uncertain. (4) Local ulceration in bronchiectasis may lead to the formation of cavities lined altogether or in part by granulation-tissue; such cavities may be described as abscesses. (5) Pulmonary embolism, even if aseptic in origin, may result in an abscess, but suppuration is usually an indication that the patient is the subject of embolic pyæmia. Abscesses in pulmonary embolism are generally small, multiple, and situated on the surface of the lung. (6) Injuries of the lung, whether resulting from external injury or inspiration of foreign bodies, may give rise to abscesses. (7) Suppuration of a hydatid cyst may cause abscess (see p. 916). (8) Abscess of the lung may result from the bursting into it of an abscess connected with some external structure, such as mediastinal abscess, suppurating bronchial gland, empyema, sub-diaphragmatic abscess, abscess from carious rib or spine, and secondary suppuration of a malignant growth of the œsophagus.

SYMPTOMS AND PHYSICAL SIGNS.—These vary with the origin and distribution of the suppuration. Their character depends primarily upon whether or not the abscess communicates with the bronchus. In the former case there will be cough and expectoration; in the latter there may be only such physical signs as are caused by a localised collection of fluid together with the general symptoms of suppuration, but often the physical signs are very slight or absent.

The expectoration may vary very much in appearance. It may have the appearance of pure pus, or be dark and chocolate-coloured. It may consist of pus mixed with mucus or saliva, which, in the case of bronchiectasis and some other conditions, will, on standing, separate into three layers. It may be free from odour or have a faint smell, or be as foul and offensive as it is possible to imagine. When the abscess is secondary to suppuration originating elsewhere, the expectoration may contain evidence of its origin, such as bile, necrosed liver-tissue, calcareous nodules, stomach-contents, portions of bone, &c. It is therefore of great importance to examine the expectoration very critically.

If the abscess be small, and does not open into a bronchus, the physical signs are often very equivocal. If it be large and has not opened into a bronchus, the physical signs will approximate more or less closely to those of an empyema, or still more closely to those of hydatid of the lung. After the abscess has established a communication with the bronchus, the physical signs of a cavity should from time to time, if not permanently, be apparent.

The physical signs of the abscess are often ob-

scured by those of the morbid condition of the lung which preceded it. See BRONCHIECTASIS.

PROGNOSIS AND TREATMENT.—The treatment of bronchiectatic abscesses is most unsatisfactory. Even if a large cavity be opened, only partial relief is obtained, as the other cavities continue to discharge. The treatment of basic tubercular cavities is on the whole satisfactory. The most promising cases for surgical interference are the chronic non-tubercular ones. The cure of an abscess may be effected by spontaneous expectoration or by surgical interference. If the spontaneous discharge be inefficient, as shown by the persistence of the general signs of suppuration, or when the abscess does not communicate with the air-passages, surgical interference should be considered. When a local abscess of the lung is suspected, exploration should be made with the aspirator. On no account should a simple exploring trocar be employed unless it has been ascertained in some way that adhesions are present. Otherwise a pneumothorax may result which, apart from the subsequent and often fatal issue, will modify the physical signs, and possibly result in the displacement of the abscess. When the presence of pus has been ascertained a portion of the chest-wall should be removed by taking away two or three inches of two or more ribs, taking care not to injure the pleura. A circle of silk or catgut sutures is then passed with a 'whole-curved' needle deep into the substance of the lung, thus attaching it to the parietal pleura. The parietal pleura and the abscess are then to be incised. As a rule this is safely accomplished by means of a narrow bistoury and subsequent dilatation of the wound by means of dressing forceps; but as there is a risk of serious hæmorrhage it has been recommended to make the incision by means of the actual cautery, and this plan has certain advantages, although the charring of the tissues renders it difficult to appreciate the condition of the lung with the finger, and makes it more likely that secondary hæmorrhage will occur at a later period. Should the hæmorrhage at the time of the operation be severe, the wound must be plugged, but it will be found, as in the case of other vascular viscera, that the bleeding has a tendency to stop spontaneously. A large drainage-tube is to be inserted into the cavity. Irrigation of the cavity is not permissible.

The treatment of pulmonary cavities by inhalations (p. 745) and intralaryngeal injections has been much practised, and, in cases which are not amenable to surgical interference, should be tried; but the results have not been as successful as it was at one time hoped they would be. R. J. GODLEE.

LUNGS, Active Hyperæmia of.—This term is employed to denote widely differing conditions.

1. The vessels in those parts of the lung immediately surrounding a patch of acute inflammation are dilated, and permit the passage of a larger amount of blood than under normal conditions, just as the corresponding vessels do in the case of any other similar foci elsewhere. These circumferential areas may be said to be in a condition of *active congestion*. It is moreover possible that the resonance over them may be slightly impaired.

2. Over-action of the right ventricle may conceivably lead to the presence of an excess of blood in the lung, though such a condition must always be temporary. It is, however, probable that excess

of blood in the vessels of the lung, when due to altered cardiac action, is always the result of defective action of the left side, or of paralytic conditions of the vessels, and is therefore more correctly described as *passive* or *mechanical*, as the case may be.

3. The term 'active hyperemia' is also occasionally applied to the distension of the bronchial and pulmonary vessels which follows the inhalation of hot air and other irritants. This condition cannot, however, be differentiated from true inflammation.

H. MONTAGUE MURRAY.

LUNGS, Amyloid Disease of.—In advanced cases of amyloid disease the lung-tissues may present more or less of this morbid change. See AMYLOID DISEASE.

LUNGS, Apoplexy of.—A synonym for extravasation of blood into the lungs. See LUNGS, Hæmorrhage into.

LUNGS, Atrophy of.—SYNON.: Senile Emphysema; Fr. *Atrophie du Poumon*; Ger. *Lungenatrophie*. See LUNGS, Emphysema of.

LUNGS, Brown Induration of.—See LUNGS, Passive Hyperæmia of.

LUNGS, Cancer of.—See LUNGS, Morbid Growths of.

LUNGS, Cirrhosis of.—A synonym for chronic pneumonia. See LUNGS, Inflammation of; D. Chronic Pneumonia.

LUNGS, Collapse of.—SYNON.: Apneumotosis; Fr. *Affaissement Pulmonaire*; Ger. *Lungen collapsus*.

DEFINITION.—Simple diminution in size of the whole or of a part of a lung, with reduction of the volume of the contained air; caused by interference with its free entrance in inspiration.

ÆTIOLOGY.—The causes of collapse of the lung are either *intrinsic* or *extrinsic*; and frequently the two classes of causes are combined. The *intrinsic* causes present actual obstruction of the respiratory passages, and include all diseases of the larynx, trachea, and bronchi attended by inspiratory dyspnoea, whether due to the pressure of external tumours, to affections of the passages themselves, or to the presence of inflammatory products, blood, or foreign bodies within them. To this class of causes belongs the collapse of the lung which is apt to follow infantile bronchitis, when the tubes become obstructed, and there is no power to expectorate. All causes that interfere with respiratory efficiency favour the occurrence of the condition named. A plug of mucus may be drawn, in inspiration, deeper and deeper into the bronchial tubes, which it obstructs, and, acting like a 'ball plug,' allows the expulsion of air in expiration, but interferes with inspiration; the air not being replaced, apneumotosis is developed; and as there is no air behind the plug of mucus, cough is powerless to expel it. In children bronchial inflammation is exceedingly common; and, the smaller tubes being proportionately smaller in the child than in the adult, the danger of collapse is increased. When children under five years of age die of bronchitis and allied affections, apneumotosis is almost invariably present; and 25 per cent. of the total mortality of infants may be safely set down to this cause. Partial collapse of the lung may follow pressure

on the respiratory passages (see MEDIASTINUM, Diseases of). The *extrinsic* causes of pulmonary collapse are certain conditions of the walls of the chest, which diminish the force of the inspiratory act, such as paralysis or debility of the inspiratory muscles, and softness of their bony attachments. Muscular paralysis is seen in injuries to the spinal cord. Debility of the respiratory muscles may often be observed before death. Collapse of the lung, apart from pleural effusion and pneumothorax, is only rarely met with in adult life, when great prostration occurs in the course of fever, and respiration is impeded by pulmonary congestion. Associated as it is with softness and weakness of the ribs, rickets is one of the most frequent causes of collapse of the lungs. The action of the inspiratory muscles may be still further interfered with by abdominal distension, or by the binding up of the abdomen of the infant with tight bandages. The danger of collapse is lessened when the ribs have gained firmness and fixity, and when, raised by the respiratory muscles, the thoracic cavity is enlarged, and the lungs are consequently expanded. Collapse resulting from admission of air to the pleural cavity is described under LUNGS, Compression of.

ANATOMICAL CHARACTERS.—The whole of one lung or of one lobe may be affected, but the condition is generally limited to individual lobules or small parts of the lung, the affected lobules being abruptly separated from those adjoining. As a rule, several patches of collapse occur in each lung, having a darker colour and more depressed surface than the healthy parts. The lower margin of the left lower lobe is most frequently affected. The collapsed portions of lung are tough and leathery in consistency; they resist pressure, are non-crepitant, are smooth on section, and sink in water. The bronchi are filled with mucous fluid; there is an entire absence of air in the collapsed parts. On inflation, the affected portion assumes a natural appearance, unless considerable congestion exists; whereas in pneumonia inflation cannot restore the lung to its natural appearance. In pneumonia pleurisy is rarely absent; but in collapse the pleura is invariably healthy.

SYMPTOMS.—The symptoms of collapse of the lung vary greatly with the cause, rapidity, and extent of the morbid condition. In severe cases, for example, in the collapse that follows bronchitis in very young subjects, the symptoms are peculiar. There are great prostration, debility, restlessness, and sleeplessness. The temperature falls; the surface becomes cold, blue, or dusky; the eyes become shrunken; and the pulse is quick and small. There is a constant feeble whining cry. Respiration is very quick and shallow, as high as 70 to 80 or even 100 per minute. The rhythm is changed, the interval being between inspiration and expiration, instead of after expiration. There is no pain as in pleurisy. The cough is constant and impotent; is often followed by a cry of impatience; and differs much from the suffocative cough of bronchitis.

On examining the chest the lower part is found retracted and diminished in diameter. The intercostal spaces sink in inspiration, and move outwards slightly in expiration. When the collapse is extensive, there are dulness and resistance on percussion, unless the affected lobules are interspersed among the healthy ones. The respiratory murmur is lost over the affected parts; though conducted breath-

sounds, of a bronchial character, and rhonchi are generally audible almost universally. In the simpler cases of collapse of the lungs, such as occur in pertussis during the severe fits of coughing, some of these symptoms and signs may be suddenly developed, and again speedily disappear.

DIAGNOSIS.—Apneumatosiis may be distinguished from croupous pneumonia by the comparative rarity of the latter disease in infancy; and by absence of the great heat of skin, and of fine crepitation on auscultation. From extensive miliary tuberculosis it is diagnosed by the absence of advancing symptoms of constitutional disorder, though the two conditions may co-exist. In pleurisy, the dulness on percussion, and the absence of respiratory sounds at the base, are much more marked than in apneumatosiis. Congenital collapse, or *atelectasis*, is a condition which has to be distinguished from infantile collapse or *apneumatosiis*. Readily separable by symptoms, these two conditions may be indistinguishable by physical signs. In atelectasis the lung retains, in whole or in part, its foetal condition, nature having failed to establish respiration and fit the child for its new mode of existence. In apneumatosiis the once permeable lungs cease to admit air, and thus death from apnoea occurs without any apparent structural change being discoverable, save that the respiratory organs bear the appearance of foetal, unexpanded lungs.

PROGNOSIS.—The prognosis in collapse of the lung is favourable if the affection is recent, and the child healthy, with fair muscular power, and under favourable hygienic conditions. On the contrary, the disease is generally fatal if it involve a considerable extent of lung, especially if it supervene on atelectasis. Death usually occurs from slow asphyxia, the effect being the same as if the size of the lung were reduced by the removal of the affected parts. As much as half of the entire lungs has been found involved, thus fully accounting for the quickened respiration, the distress, and the dyspnoea, and for the bloodlessness and extreme pallor, with cold blue extremities. The fatality of whooping-cough in infants is mainly due to the ready collapse of the lungs, especially when the child is badly nourished and breathing impure air. The natural course of the disease is from bad to worse: more lung is involved each day; and death occurs after two or three weeks from slow asphyxia. If collapse follows acute bronchitis, death often ensues rapidly; but if recovery takes place, the lungs are slow to regain activity, and the seeds of future mischief may remain. After an attack of pneumonia, complete absence of breath-sounds may exist for a time, and then suddenly—after a blow, shock, or violent cough—air enters the collapsed portion of lung, and the respiratory sounds assume a normal character.

TREATMENT.—Slight counter-irritation, by means of stimulating embrocations, is useful. An emetic of ipecacuanha will help to remove accumulation if the patient is not too weak. Expectoration may be promoted by small doses of similar drugs (*see* EXPECTORANTS). When the lungs are extensively involved, vital power must be kept up by the help of ammonia, perchloride or phosphate of iron, port-wine, beef-tea, and other stimulants; and the food must be selected so as to be digestible by the stomach of the infant.

E. SYMES THOMPSON.

LUNGS, Compression of.—SYNON.: Fr. *Compression du Poumon*; Ger. *Lungen-compression*.

DEFINITION.—Diminution in size of the whole or of a part of a lung, associated with reduction of the volume of the contained air; caused by pressure on the pleural surface.

ÆTIOLOGY.—Compression of the lung may arise in the course of numerous diseases or injuries affecting the chest; the compressing influence being either gaseous, liquid, or solid. The first effect of any of the causes is to permit *collapse*; only when the action of the elastic tissue of the lung ceases does actual *compression* begin.

First, the admission of *air* to the pleura from without through a perforating wound, as from a sword or bayonet thrust; or from within, as by rupture of an air-cell, or the extension of pulmonary ulceration through the pleura, produces in either case compression. If no previous pleurisy has existed and no free opening is present, the compression is complete; but if, on the other hand, long-standing pleurisy has caused adhesion; compression cannot take place, or will be but partial.

Secondly, compression may arise from the presence of *fluid*, such as pleuritic effusion, acute or chronic; passive non-inflammatory effusion, as in hydrothorax; or blood, as in hæmorthorax.

Thirdly, compression of the lung by *solids* is seen in the case of various tumours of the chest, whether originating in the mediastinal structures, in the lungs, or in the thoracic parietes.

In the fourth class of cases compression of the lung is the result of the enlargement of neighbouring parts, other than the thoracic viscera; and especially of the abdomen, as in ascites, and tumours of the liver, spleen, or ovaries.

ANATOMICAL CHARACTERS.—Compression of the lung may be either general or local, complete or partial. A lung compressed by pleuritic effusion is found to be reduced in volume, non-crepitant, dense, but not quite insusceptible of inflation. The blood is coagulated in the affected lobes, the clot being often decolourised and adherent to the walls of the vessels, many of which are impervious, or altogether obliterated; while the pervious vessels and the air-cells of the adjacent parts are distended, and emphysema is produced. In other cases the compressed lung proves to be anæmic, tough, and dry.

In cases of slow recovery from chronic empyema the lung is often found bound down and thickened. The portion of the thoracic cavity vacated by the shrunken lung is occupied by the displaced heart, and sometimes by the extension of the sound lung across the middle line.

SYMPTOMS AND PHYSICAL SIGNS.—The symptoms of compression of the lung vary greatly in accordance with its causes, the rapidity of onset, and the extent and degree of compression. If pleuritic effusion be very rapid the dyspnoea may be exceedingly urgent. After perforation of the pleura with sudden collapse of the lung there also occur acute pain, dry cough, and painful spasms of the intercostal muscles. The pulse is frequent, feeble, and often irregular. Symptoms, more or less acute, of inflammation may follow. In other instances the symptoms are those of hydrothorax or of intrathoracic tumour.

The physical signs of compression of the lung are chiefly those of the associated cause, such as pneu-

mothorax, pleurisy, hydrothorax, or intrathoracic tumour; and partly certain phenomena characteristic of the physical condition of the lung itself. The latter vary considerably with the degree and extent of compression, but they may be described in general terms as follows: Either increased clearness of the percussion-sound over the area of compressed lung, with tubular or rarely even tympanitic quality, especially in children, or in extreme cases of compression complete loss of resonance; indefinite, weak, but occasionally rather blowing or tubular respiratory sound, sometimes mixed with scanty, dry, subcrepitant rhonchus; and exaggerated loudness and ringing quality of vocal resonance. A further description of these symptoms and signs will be found under the headings of the various causes of compression referred to.

DIAGNOSIS.—The diagnosis of compression of the lung is in general simply the diagnosis of the condition on which it depends.

PROGNOSIS.—The prognosis depends on the cause of the compression. Thus in pneumothorax it is unfavourable, though recovery may take place. In hydrothorax the ultimate prognosis is unfavourable, as it is usually an evidence of formidable, if not incurable, organic disease. In pleurisy, if the effusion has been rapid, met by prompt treatment, and uncomplicated with tuberculosis, complete recovery may take place without much compression of lung or distortion of chest; but pleurisy is too frequently the first incident in the development of phthisis. In empyema the prognosis is more favourable than in pneumothorax or hydrothorax.

TREATMENT.—Little need be said as to the treatment of lung-compression. It resolves itself into that of the primary or causative diseases. Bearing in mind the injury done to the lung by compression, efforts should be made to relieve the lung before it has been irremediably bound down. The early adoption of paracentesis thoracis is the most practical means of gaining this end in pleuritic effusion. Remedies calculated to remove effusion and thus relieve the lung should be given, remembering that the more speedy the relief given to the lung the more complete will be the cure. Suitable movements of the chest might be ordered subsequently, with the view of promoting expansion of its walls and of the lung. Nor must a mention of the value of elevated health-resorts, the Engadine for instance, be omitted as a means of promoting the expansion of a lung which has been compressed.

E. SYMES THOMPSON.

LUNGS, Congestion of.—See LUNGS, Hyperæmia of.

LUNGS, Consumption of.—See PHTHISIS.

LUNGS, Embolism of.—See LUNGS, Hæmorrhage into.

LUNGS, Emphysema of.—SYNON.: Fr. *Emphysème du Poumon*; Ger. *Lungenemphysem*.

DEFINITION.—An excess of air in the lungs, whether due to a dilated condition of the air-sacs, or to the presence of air in the interlobular tissue.

VARIETIES.—There are two forms of emphysema of the lungs, namely: A. *Vesicular Emphysema*. B. *Interlobular Emphysema*.

A. **Vesicular Emphysema.**—Vesicular pulmonary emphysema exists in three forms, namely, (1) *partial lobular*; (2) *lobular*; and (3) *lobar*. The last form involves the whole of a lobe, or the

whole of one or both lungs. The first form is rarely seen alone, but is generally associated with the second form, which is very common, and is found in connection with diseases, such as bronchitis, which are attended with violent or long-standing cough. The third form is by far the most important, and will be more especially referred to in the present article. It more frequently attacks both lungs than one, and the lower as well as the upper lobes. It is a serious malady, and sometimes destroys life at an early period. Its features are characteristic: the lung-substance has a peculiar doughy feel; pits on pressure; is wanting in healthy crepitation; and has a pale pink colour very closely resembling that of a calf's lung. It has been described as 'large-lunged vesicular emphysema.'

ETIOLOGY.—*Determining causes and mechanism.*—With reference to the determining causes of emphysema, there are two theories, namely, the inspiratory theory, and the expiratory theory. On the first view the dilatation and rupture of the air-sacs are accounted for by the over-distension of the lungs in inspiration. On the second view these changes are considered to be caused by the strain to which the lung-tissue is subjected in violent expiratory efforts, especially the act of coughing. It has been thought by others that emphysema must be looked upon as a complementary lesion, arising in consequence of the over-distension to which the healthy portions of the lungs are subjected in cases of pulmonary collapse. Without entering into any critical examination of the theories as to the mechanical causes of emphysema, it may perhaps be sufficient to say that there can be little, if any, doubt that the lobular forms of the disease are mainly produced by expiratory efforts, such as violent cough, or blowing wind-instruments. They have their seat in those parts of the lungs which become most distended by such acts. With regard to the lobar form of the disease, however, this explanation of its mechanism does not suffice. In this affection the inspiratory power is that which distends the lungs. The pulmonary tissue has lost a portion of its elasticity, it yields to distension, and no longer reacts perfectly when the distending power ceases. Further distension follows; reaction diminishes still more; until at length in some instances the lungs become greatly enlarged.

In senile cases the loss of elasticity of the chest-walls aids in preventing the pulmonary reaction.

ANATOMICAL CHARACTERS.—In the early stages of emphysema there is simply a dilatation of the air-sacs; an increase in the size of the alveoli; and a diminution in the extent of the alveolar walls, which, yielding with the distending cavities, become partially obliterated. As the disease progresses, the air-sacs become more distended and the walls of the alveoli sometimes completely obliterated, so that the air-sacs are quite smooth, instead of honey-combed. Then follows perforation of the air-sacs—at first slight, here and there an oval opening being discoverable; afterwards the openings become larger and more numerous. The subsequent progress of the disease is attended with further distension of the air-sacs, and rupture of the fibres of their walls. The openings thus caused coalesce, until at length the walls are simply represented by membranous shreds, and even large vesicles may form. These changes, varying in degree, characterise all the forms of emphysema. In the lobar form, however, perforation takes place to a much greater

extent, relatively to the amount of dilatation, than in the lobular or partial lobular form.

The emphysematous lung is anæmic; and its blood-vessels become widely separated, and often ruptured and atrophied. The bronchial tubes are sometimes dilated, especially in old-standing cases, and in these there is frequently found an increased development of the circular muscular fibres.

There is a form of lobar emphysema which is met with in old age, and which differs in some respects from that already described. The lungs are not so large; they are universally distended, however, to a greater or less extent; and they present a somewhat atrophied appearance. The alterations, of which they are the seat, are probably the result of those changes which age produces in the chest-walls, impairing their elasticity. This loss of elasticity may also affect the lung-tissue.

SYMPTOMS.—A constant and gradually increasing dyspnoea is one of the most important and most frequent of the symptoms of emphysema. Bronchitis, and therefore cough, with expectoration, is generally present. Hæmoptysis is rare, and, when it does occur, is slight. The patient is usually free from pain, but complains of a feeling of oppression, or a 'smothering in the chest.' In severe cases of lobar emphysema this last symptom and the dyspnoea are often the only circumstances which attract the attention of the sufferer to his malady. In other instances, however, and especially when the disease is only partial, a close examination will elicit the fact that there have been bronchitic symptoms. Few cases of emphysema exist for any length of time without the occurrence of asthmatic seizures. In advanced cases the aspect is peculiar. The countenance is dusky, leaden, and puffy. The nostrils are dilated, and expand widely on inspiration, while the angles of the mouth are drawn down. The voice is feeble. The whole body has a cachectic appearance, and is sometimes much wasted. General dropsy often ensues.

The lungs being the seat of general expansion, the thorax is kept abnormally distended. Thus it can undergo but little enlargement at each inspiration. As there is no impediment to the passage of air to the air-sacs, inspiration is accomplished rapidly. Not so, however, with expiration. The lung-tissue has in great measure lost its elasticity, and reacts slowly after distension; and this results in laboured, slow, and ineffectual efforts to expel the air. Further, as the lungs are more or less riddled with perforations, their aerating surface is diminished, and this necessarily causes dyspnoea whenever any increased demand is made on the respiratory function. The quantity of blood circulating through the lungs, even from the earliest stages of the affection, is also diminished; and the destruction of the capillary vessels, which ensues when the disease is more developed, further decreases the vascularity of the pulmonary tissue. Hence its pale, anæmic appearance after death, a circumstance which serves to explain how rarely it is the seat of pneumonic inflammation.

PHYSICAL SIGNS.—Among the most important of the physical signs of emphysema are the following: The upper part of the chest and the clavicles are prominent; the neck seems shortened; the fossæ above the clavicles are deepened; there is increased curvature of the dorsal spine; and the sternum is arched. The gait is stooping; the ribs are prominent; and the intercostal spaces are de-

pressed. There is indeed a general increase in the size of the chest, usually most marked at the upper part. These are the features of the disease when it is extensive. If partial, or confined to one lung or part of a lung, the prominence of the chest exists on one side only, and the other symptoms and signs are less marked. The movements of the chest in respiration are peculiar. The breathing is for the most part superior thoracic, but the chest is not much expanded on inspiration, for the lungs are already inordinately distended. The lower end of the sternum and the lower ribs are drawn in during inspiration. In some cases during inspiration there is marked protrusion of the abdomen. The respiration presents other features. The inspiration is short and quick, and is followed by a prolonged and often wheezy expiration. Coughing is performed feebly, and expectoration is attended with difficulty. Percussion and auscultation elicit important diagnostic marks of the disease. When it is general there is increased, and in some instances almost tympanitic, resonance over the whole of the chest, most marked towards the apices of the lungs, and along their anterior borders; and in partial cases almost confined to these spots, or to one side. The præcordial region is generally resonant, owing to the distended lungs coming between the heart and the wall of the chest; and the cardiac impulse can often be felt beneath the lower end of the sternum. The respiratory murmur is faint, and characterised by peculiarities which a knowledge of the anatomical condition of the lungs and of the chest-walls enables us to explain. The inspiratory murmur is short, and is followed by a prolonged expiratory murmur. This latter is unlike the sound heard in any other affection, and is, in fact, pathognomonic of emphysema. In some advanced cases the respiratory sounds are scarcely audible, if the bronchial tubes are free from mucus, and no spasm exists. A *râle* is often heard in emphysema, but it is not a 'dry *râle*.' It is probably produced in the finest bronchial tubes, and is a modification of the sub-crepitant *râle* of bronchitis. Although valuable in aiding diagnosis when present, yet, from its frequent absence and the difficulty of distinguishing it from the ordinary sub-crepitant *râle*, it loses much of its diagnostic import.

COMPLICATIONS AND SEQUELÆ.—Bronchitis is one of the most frequent of the diseases associated with emphysema of the lungs. It is rare for the latter affection to exist for any length of time without the supervention of the former. Bronchitis presents some peculiarities when it affects an emphysematous lung. It is rather the result of congestion than of inflammation. It often attacks the finer bronchial tubes; and, when severe, is attended with profuse secretion—a circumstance which, coupled with the fact that expectoration is less easily accomplished than when the lungs are healthy, seriously complicates the affection, and increases the danger of death from asphyxia. The inflammation sometimes runs on very rapidly, and copious purulent or puriform expectoration occurs. Even when this is the case, an examination of the tubes after death may reveal but little vascularity of the mucous membrane. These severe bronchitic attacks are very apt to be attended by the formation of fibrinous clots in the heart and the large vessels arising therefrom. Bronchitis, in a subacute or chronic form, is a very constant cause of winter cough in emphysematous patients.

Asthma, occurring with greater or less severity, is a frequent attendant on emphysema. The attacks come on for the most part during the night, and may possibly be due to the congestion of the lungs which takes place during sleep, or when the body is long in the recumbent posture. This congestion probably sets up an irritation, which gives rise to reflex spasm of the bronchial muscular fibres.

Secondary affections of the heart are constantly met with in advanced cases of emphysema. Many pathologists have believed that the right cavities alone become affected; but more recent observations have shown that the cardiac disease is not confined to one side. There is, in extensive emphysema, a general hypertrophy of the heart, with dilatation of all the cavities, especially of the ventricles. But hypertrophy is not the only change which takes place—valvular disease is frequently found. The deposits and thickening which occur about the valves are no doubt secondary to the changes in the muscular walls, and must be attributed to the general malnutrition produced by the disease. It is not difficult to understand how it happens that in emphysema there is general cardiac hypertrophy. The impediment which exists to the circulation of the blood through the lungs necessarily gives rise to an overloaded state of the right side of the heart; hence result increased action of the right cavities, and hypertrophy of their walls. Again, the overloaded state of the venous system, and the consequent impediment to the capillary and arterial circulation, call for increased action of the left ventricle; and this is followed by its dilatation and thickening. There exists also another cause, which probably has some influence in producing this cardiac hypertrophy, namely the altered position of the heart. This organ is pushed downwards, and its impulse is often felt strongly in the epigastrium. The position of the ventricles is therefore changed, and the direction of the axis of their cavities is altered with reference to that of their great vessels. This must lead to embarrassment of the circulation.

As a consequence of the changes in the heart and venous system in emphysema, dropsy often results. Many cases go on for a long time without any dropsical symptoms, while in others there is only slight oedema of the legs. In advanced cases, however, there is frequently general dropsy complicated with albuminuria.

General emphysema is attended in its progress by symptoms of cachexia and anæmia. In some cases there is much wasting of the muscular system, even before dropsical effusions occur. Further, the patients often have a sallow and anæmic appearance, not unlike that met with in renal and other serious organic diseases. There has been an impression that emphysema and phthisis are incompatible diseases, but recent researches have shown that this view is not correct. Indeed, in most cases of death from phthisis, patches of emphysema, involving the whole or part of a lobule, are met with; and doubtless have been produced by the fits of coughing so common in the disease. But the great question is whether tubercular deposit ever takes place in lungs which are the seat of lobar emphysema; and this question must be answered in the affirmative, although the concurrence of the two diseases is uncommon. Pneumonic consolidation is very rare in an emphysematous lung.

Pleurisy not infrequently exists in connection with emphysema; pleuritic adhesions being often

found after death. The occurrence of pleurisy must, however, be considered as an accidental circumstance. In the most extensive cases of emphysema pleuritic adhesions may not be found.

PATHOLOGY.—When the disease is partial, and has followed or is attended by bronchitis, or some other affection in which there has been violent or long-standing cough, the emphysema may be the result of mechanical violence, without pre-existing degeneration of the lung-tissue. When, however, it is of the lobar form, degeneration is probably the primary step in the affection. The facts which tend to confirm this view are: (1) the insidious manner in which the disease sometimes comes on, and the development which it attains, without any previous history of violent or long-standing cough; (2) the frequency with which it attacks the whole of both lungs; and (3) its hereditary character. The exact nature of the degeneration has not been satisfactorily made out. Fatty matter has been found in a few instances, but not in all cases. The degeneration is probably one primarily involving the elastic fibres and other structures of the walls of the air-sacs. Whatever be the nature of the degeneration, there can be no doubt that lobar emphysema is a malady resulting from some form of malnutrition of the lung-tissue. There is reason to believe, too, that this form of emphysema is sometimes associated with gout.

TREATMENT.—This must be referred to under two heads, namely (1) the treatment of *the disease*; and (2) that of *the secondary affections*, which follow or are associated with it.

1. *Treatment of the Disease.*—It can scarcely be expected that, when once perforation and rupture of the air-sacs have taken place, the normal condition of the lung can be restored. But, while we admit this, it is by no means implied that the disease is beyond control. That condition of lung-tissue which precedes the perforations—the simple distension of the air-sacs—admits of great amelioration, and further degenerative changes may be, if not prevented, at least much retarded.

All measures which tend to invigorate the system, to give tone to the heart, and to improve the condition of the blood, should be resorted to. Among the remedies for internal administration the most useful is iron. It should be given in small and continued doses. Quinine is valuable, as are also the various bitters and other remedies for dyspepsia, from which emphysematous patients often suffer. Cod-liver oil is very useful in some cases. Strychnine has been recommended with the view of improving the tone of the muscular fibres of the bronchial tubes. It has not been found useful in this respect; nor need we wonder at this, for the disease is one primarily of the air-sacs, and not of the bronchial tubes, and, if the muscles of the latter are secondarily affected, it is rather with spasm than paralysis. Small doses of strychnine given for dyspeptic symptoms may be useful. In some cases iodide of potassium has apparently been beneficial. Probably these cases have been associated with gout.

Breathing compressed air has been strongly advocated, and no doubt it has afforded in some cases decided temporary relief, and good effects are said to have followed its use. See AIR, Therapeutic Use of.

The regulation of the diet, and the general management, are most important. The diet should

be nourishing, and a moderate amount of stimulants should be allowed. The food should be easy of digestion, and nutritious in proportion to its bulk. The stomach should never be overloaded, as that condition will give rise to dyspnoea. Errors of diet must be avoided, and the functions of the bowels should be carefully regulated. Another point is to give the lungs as little work as possible, and to let the patient breathe a pure air. All violent exercise, or physical exertion of any kind, must be strictly prohibited; moderate exercise is, however, to be recommended. Moderate walking, yachting, carriage-exercise, riding at a quiet pace and on an easy horse, are important adjuvants in the general treatment of emphysema. The condition of the skin should be carefully looked to; warm clothing should be constantly worn; and the greatest care should be taken to ward off bronchial inflammation. Residence during the winter in a warm and dry climate is to be recommended.

2. *Treatment of Secondary Affections.*—Among the most important of the affections secondary to emphysema is bronchitis. No depressing measures should be used in this disease, but such as will promote expectoration, and check the secretion of the bronchial tubes, if, as is very frequently the case, this be excessive. Ammonia, the various stimulating expectorants, and iron are the most valuable remedies, together with moderate counter-irritation (*see BRONCHITIS, Diseases of*). The dyspnoea attendant on emphysema admits only of palliative treatment, but is often greatly improved by the observance of the rules laid down for the general management of the disease. The dyspnoea is always increased by the presence of bronchitis; by the stomach or bowels being overloaded; and by the general over-distension of the venous system, which necessarily ensues as a consequence of the impediment to the flow of blood through the lungs. Care should be taken to prevent any flatulent distension of the stomach or intestines, and to keep up a good action of the bowels, liver, and kidneys. For the relief of the asthma which frequently exists in connection with emphysema, full doses of iodide of potassium are often useful. Stramonium may also be smoked, and other measures beneficial in ordinary spasmodic asthma may be tried (*see ASTHMA*). In reference to the treatment of the dropsical symptoms, which follow as a secondary consequence of emphysema, the reader is referred to the articles DROPSY; and HEART, Dilatation of.

B. *Interlobular Emphysema.*—This condition, in which the excess of air in the lungs is contained, not in the air-sacs and alveoli, but in the connective tissue between the lobules, is described under the head of EMPHYSEMA, SUBCUTANEOUS, to which article the reader is referred.

LUNGS, Gangrene of.—SYNON.: Fr. *Gangrène du Poumon*; Ger. *Lungenbrand*.

DEFINITION.—Death of a portion of the substance of the lungs.

Gangrene of the lungs is of two kinds, namely, (1) *diffused*, in which the whole of one lobe or lung is affected; and (2) *circumscribed*, in which a portion only of a lobe undergoes gangrenous change.

ÆTIOLOGY.—Gangrene is sometimes a result of acute pneumonia, or of the local action of other toxins. It has been known to follow the inhalation

of noxious gases. Its occurrence is favoured by extreme constitutional depression, or by pressure interfering with the circulation and nutrition of the lung. An aneurysm or mediastinal growth, pressing upon the main arterial, venous, and nervous trunks at the root of the lung, is perhaps the most common antecedent of diffused gangrene; whereas the more circumscribed form of the disease is a sequela of acute and limited pneumonia, cancer, bronchiectasis, or rapid phthisis in a debilitated subject. In pulmonary apoplexy and other operations on the mouth septic infection may lead to gangrene, the gangrene being limited to the portion of lung involved in the original extravasation of blood. Pneumonia caused by a foreign body in the air-passages is apt to run on to gangrene. The diffused gangrene that occurs in drunkards and lunatics, in measles, small-pox, and typhus, evidences excessive nerve-prostration and loss of nutritive power. In children, gangrene of the lung sometimes follows cancrum oris, as well as the eruptive fevers.

ANATOMICAL CHARACTERS.—The colour of a gangrenous lung is dark, dirty olive, or greenish-brown. It is moist or even wet; and either of the consistence of engorged lung, or softer and more diffident. The odour is that of external gangrene or decomposed flesh, and is distinctive during life, rendering the room in which the patient lies horribly offensive. When scattered patches of gangrene occur, there is often in one part a solid mass of greenish lung-tissue, and in another a central sloughy or gangrenous cavity, surrounded by a broad rim of soft infiltrated lung. The seat of circumscribed gangrene is usually the periphery of the lung and the lower lobes. If a bronchus open into the gangrenous patch, inflammation of the bronchial membrane is set up. In rare cases the pleura is involved, and pyo-pneumothorax is induced. Sometimes the pulmonary arteries are found plugged, and more often the bronchial arteries. In those rare cases in which recovery takes place, interstitial pneumonia is set up, leading to encapsulation of the gangrenous spot; the sloughs are ejected; and cicatrization follows, as in pulmonary abscess. *See LUNG, Abscess of.*

In diffuse gangrene the whole of one lung is sometimes involved. The pulmonary tissue is then converted into a black putrid substance, saturated with blackish purulent fluid; or the gangrenous part merges gradually into oedematous or hepatized tissue.

Embolism, arising from the introduction of septic matter into the veins, and leading to abscess in various organs, may follow either form of gangrene. Secondary gangrenous change is frequently met with in other parts of the same or in the opposite lung.

SYMPTOMS.—It is seldom possible to diagnose gangrene of the lung until the purulent discharge reaches a bronchus and is ejected. Then the sputa are found to separate speedily into layers—a superficial froth, a liquid middle layer, and a lower sediment. The smell of the sputa and breath is excessively fetid. The dyspnoea and prostration are usually great. The physical signs are those of softening and excavation, percussion being either dull or tympanitic, and loose crepitation being soon replaced by gurgling and perhaps amphoric breathing. The passage of the circumscribed into the diffused form may be traced by watching the physical signs.

DIAGNOSIS.—Suppurative ulceration of the bron-

chial cartilages gives rise to great foetor of breath. Sometimes a gangrenous odour in the breath occurs when the putrefactive change is limited to the secretions; and it may be present also in pyo-pneumothorax with internal fistula. These several diseases must be excluded by a careful estimation of the history and the physical signs. See BREATH, The.

PROGNOSIS.—The prognosis of pulmonary gangrene is hopeless in the diffused form; and is doubtful, even when the symptoms or signs point to a limitation of the mischief.

TREATMENT.—Every attempt must be made to support the strength by nourishing food and stimulants; bark and ammonia, quinine and acids, iron and cod-liver oil being indicated. The inhalation of creosote or carbolic acid in spray may be tried, or of turpentine on hot water (p. 745).

When a gangrenous abscess of the lung exists, and it is evident that the passage of foetid matters through the bronchi is setting up dangerous irritation, leading to exhausting discharge, or threatening to poison the system, the question of draining the gangrenous cavity should be entertained. The introduction of a drainage-tube sometimes affords immediate relief in such cases. The foetor of breath ceases; the offensive secretions, being no longer locked up in the lung, lose their putrescent character; and the relief to the constitution is great. An accurate diagnosis is in such cases essential, the danger of the operation being somewhat enhanced if the abscess is at a distance from the chest-wall, and if the lung is not adherent to the costal pleura. For a detailed account of the necessary operation see LUNG, Abscess of.

Besides the general treatment which co-existing disease may require, special attention must be given to the removal of the gangrenous odour from the atmosphere of the room, from the sputa, and from the patient, who is apt to exhale from the skin a similar odour to that given off in the breath. Sulphurous acid, carbolic acid, or chlorinated lime fulfils the first indication; Condy's fluid the second; and the latter may also, when diluted, form a useful wash or gargle. See INHALATIONS.

E. SYMES THOMPSON.

LUNGS, Hæmorrhage into.—SYNON.: Extravasation of Blood into the Lungs; Pulmonary Apoplexy; Fr. *Hémorrhagie du Poumon*; Ger. *Lungenblutung*.

ÆTIOLOGY AND PATHOLOGY.—In the article HÆMORRHAGE will be found enumerated the causes which lead to pulmonary hæmorrhage. In the present article only those extravasations of blood into the lungs are included which do not depend upon direct injury to the organ, or upon exposure and rupture of vessels in the course of destructive disease affecting it.

Hæmorrhage into the substance of the lungs may be *diffuse*, *punctiform*, or *circumscribed*.

(1) *Diffuse pulmonary apoplexy.*—The diffuse extravasation of blood into the lungs is an extremely rare condition. Some cases have been recorded, however, in which it has arisen from primary disease of a branch of the pulmonary artery. The lung-tissue is broken down by the hæmorrhage into it; and the patient soon succumbs.

(2) *Punctiform hæmorrhage*, and (3) *circumscribed or nodular pulmonary apoplexy*, are not of uncommon occurrence, and are attendant upon the same morbid conditions of the lung. Mitral disease

—mitral stenosis especially, but also mitral regurgitation—is the chief remote cause of these two forms of pulmonary apoplexy.

In the so-called 'hæmorrhagic diseases of the blood,' punctiform hæmorrhage in the lungs is possible; but petechiæ more frequently affect the pleural surface or bronchial mucous membrane (see HÆMORRHAGE). Mechanical congestion of the lungs, from the above-mentioned forms of heart-disease, is by far the most common condition upon which this minute and interstitial form of hæmorrhage supervenes, giving rise to no additional symptoms, but causing considerable and peculiar pigmentation of the lung. The interstitially thickened lungs acquire a brownish tint, from the absorption of the blood-spots, leaving hæmatin behind; and the appearance has given rise to the term *brown induration* of the lungs. See LUNGS, Hyperæmia of.

Nodular or circumscribed pulmonary apoplexy is often associated with the petechial hæmorrhage just described, and, like it, mostly supervenes upon the mechanical congestion of the lungs arising from heart-disease. There are two ways in which this form of hæmorrhage may be produced. The first way is by rupture of capillaries or small veins under the heightened pressure of the pulmonary circulation. An effusion of blood thus occurs, which fills up one or more lobules, and coagulates to form the dark firm consolidations so characteristic of the lesion. Or a branch of the pulmonary artery becomes obstructed by an embolus, for instance, by a fragment of coagulum conveyed from the right auricle, or from one of the systemic veins (phlebitis, varicose veins); and its territory becomes at once filled with extravasated blood. See EMBOLISM.

ANATOMICAL CHARACTERS.—A lung that is the seat of this form of hæmorrhage is usually toughened and heavy. Some hard, and more or less square, flat surfaces may be felt and seen raised above the general surface of the lung, which has shrunk below their level. The pleura covering such patches is darkened in colour, and presents flakes or granulations of lymph, impairing its translucency and smoothness. On making a vertical section through one of the surfaces, it is found to form the base of a more or less conical mass, which has a firm section like damson-cheese, and is sharply defined from the surrounding tissue. In its axis is seen a branch of the pulmonary artery, occupied by partially altered clot. There is usually some staining of the pulmonary tissue immediately surrounding the apoplectic nodule, from imbibition. Such hæmorrhagic nodules vary greatly in number and size; there are usually several in each lung, of about the size of a walnut; but one may occupy a whole lobe. They also vary in appearance according to the date of their occurrence; their colour, at first that of dark blood-clot, passes through pale chocolate to yellowish-red or pale yellow, as the colouring matter becomes gradually absorbed. The whole extravasation may be gradually and completely absorbed, leaving the restored lung but little damaged; or a shrunken fibrinous deposit or blood-cyst, with surrounding induration, more rarely a calcareous centre, may mark the site of former hæmorrhage. It should be added that these extravasations, although generally near the pleural surface of the lung, are not always so, but may occur deeply in its substance; they occur more frequently in the right lung, and generally in the upper lobe.

SYMPTOMS.—Amid the symptoms attendant upon the conditions leading to pulmonary apoplexy, it is difficult to single out any diagnostic of this special lesion. An exacerbation of dyspnoea already terrible enough, or a sudden failure of pulse, may perhaps be noted. Dark scanty hæmoptysis is, however, the pathognomonic sign, the frothy mucous expectoration containing some streaks, or small clots, of dark coagulated blood. Some circumscribed patches of dulness, with bronchial breathing and neighbouring crepitation, may perhaps be made out, especially in the mammary and mid-axillary regions.

PROGNOSIS AND TREATMENT.—These lesions are among those which often close the scene in the heart-disease to which they are accessory; and are therefore irremediable. Sometimes when, from any cause, their occurrence appears to have been hurried forward; when the lividity is great, the dyspnoea urgent, and yet the disease is not of long duration; wet-cupping or bleeding from the arm will certainly give temporary relief, and perhaps avert immediate danger.

R. DOUGLAS POWELL.

LUNGS, Hydatids of.—**SYNON.** : Fr. *Kystes Hydatiques du Poumon*; Ger. *Lungenechinococcus*.

DEFINITION.—A disease due to the presence of hydatids in the lungs.

ÆTIOLOGY.—Hydatid cysts in the lungs rarely occur in this country as a primary disease of these organs, but they are not infrequently met with as an extension of disease from the liver.

In Australia, where the affection is very common, it is sometimes met with in the lung without any other organs being affected. Of 100 cases, the liver was the organ affected in 70, the lung in 12.

ANATOMICAL CHARACTERS.—Single sacs or acephalocysts (p. 461) are by far most usual, varying in size from a pigeon's egg to a man's fist. Sometimes the upper and sometimes the lower lobes are the seat of the cysts.

If the parent-sac be destroyed by inflammation and consequent suppuration, a communication is established between the cavity and the bronchi, through which the daughter-cysts may be ejected. Not infrequently the pulmonary sac communicates with a similar sac in the liver. It is natural to infer in such cases that the disease originated in the liver. Indeed, it has been stated that primary hydatid of the lung is unknown.

SYMPTOMS AND PHYSICAL SIGNS.—Hydatids may exist in the lung for a considerable time without giving rise to any noticeable symptoms; but as the tumour enlarges and presses upon the surrounding tissues, hæmoptysis occurs, as also bronchitis, pneumonia, or even gangrene. Sometimes the cysts perforate the pleura and cause pneumothorax.

If the site of the tumour be superficial, altered breath-sounds and percussion-note may be observed; but if it be deeply seated, the physical signs may escape detection. If bronchitis or pneumonia be set up, the signs and symptoms of these disorders mask those of the originating disease. Often the symptoms are like those of rapid phthisis, namely, cough, muco-purulent expectoration, hæmoptysis, night-sweats, and emaciation. The meaning of these symptoms is apparently confirmed by the physical signs, namely, dulness on percussion; absence of breath-sounds, or prolonged expiratory murmur; and, when the cysts burst, gurgling and pectoriloquy. Unless the daughter-cysts or hook-

lets are expectorated, there is nothing to point unmistakably to the nature of the disease. When perforation of the diaphragm occurs, hepatic symptoms or those of pleurisy supervene. The patient looks anxious; the features are collapsed; the skin is clammy and livid; the extremities are cold; incessant paroxysmal cough occurs, with vomiting; and by degrees sallowness and jaundice make their appearance. Symptoms of acute pneumonia may occur—of consolidation, followed by excavation; the expectoration being at first rusty, then bile-tinged, muco-purulent, and fetid, and containing, besides shreds of lung-tissue, entire cysts or portions of them.

DIAGNOSIS.—It may be difficult to distinguish a large hydatid cyst from pleuritic effusion, as the lung may be displaced, the chest bulges, and the intercostal spaces become prominent and fluctuating. The rounded outline of the dull space, the absence of acute symptoms, the history of gradual onset, the absence of ægophony and of alteration of physical signs on change of posture, will guide the decision; and an exploratory puncture, which gives exit to a clear saline non-albuminous fluid, containing possibly hooklets or fragments of cysts, will confirm the diagnosis. The conduction of the heart-sounds and impulse, and the tense unyielding condition of the bulged side on palpation, may lead to the suspicion of mediastinal tumour; but in the case of hyatids there is seldom any visible venous engorgement, or laryngeal or cesophageal pressure-sign, as in aneurysmal or other mediastinal growths. There is, moreover, generally a freedom from cachexia or constitutional disturbance. In circumscribed abscess the neighbouring lung is rarely so free from disease as in hydatid.

PROGNOSIS.—Although the symptoms may be so severe as to threaten immediate death from suffocation, recovery occurs in at least half the cases in which hydatid disease begins in the lung, and one third of those in which it spreads from the liver. If the cyst is allowed to burst of itself, recovery takes place in from 30 to 40 per cent. of cases. But the mortality is greatly reduced by early operation.

TREATMENT.—The surgical treatment of hydatid of the lung should be undertaken as soon as the disease is diagnosed because the risks involved in delay are greater than those dependent on surgical interference. If left untreated the patient is liable to (1) suffocation from rupture of the cyst into a bronchus; or (2) a probably incurable hydro-pneumothorax from rupture of the pleura. It is seldom permissible to *aspirate* a pulmonary hydatid which has not suppurated, because this procedure has more than once been followed by the simultaneous rupture of the cyst into a large bronchus, and the consequent suffocation of the patient from the rapid flow of large quantities of hydatid fluid into the air-passages. The position of the cyst having been localised a free opening should be made by removing two or three inches of two or possibly three ribs, great care being taken not to open the pleura. Fully curved needles threaded with silk or catgut should then be passed through the pleura into the subjacent lung in a continuous series round the margin of the circle of pleura exposed. It is possible if the cyst be thin that the sutures may cut through and the fluid may leak out alongside them, but this does not involve any serious risk, whereas opening the pleural cavity without thus stitching up the lung may result in the production of a pneumothorax.

If the cyst be old and thick-walled there is no chance of this happening, nor would it occur if lung-tissue intervene between the hydatid and the surface. As soon as the cyst or the lung is fixed to the parietal pleura it may be opened by a free incision and drained like any other pulmonary abscess. This treatment is especially applicable to those cases in which suppuration has occurred. Convalescence is likely to be slow. The operation may, if desired, be performed in two stages.

It must be remembered that hydatids of the lung are not infrequently multiple, and that at least in the experience of one of the present writers (R. J. G.) it is not very unusual for tuberculosis to occur in a lung which has been operated on for hydatids.

E. SYMES THOMPSON.

R. J. GODLEE.

LUNGS, Hyperæmia of, Passive.—Passive hyperæmia of the lungs may be conveniently divided into two varieties: (1) that occurring in debilitated subjects and due to general causes (*Hypostatic Congestion*); and (2) that resulting from obvious mechanical obstruction, such as mitral stenosis (*Mechanical Congestion*), and leading to Brown Induration.

Hypostatic Congestion.—**ÆTIOLOGY.**—Passive or hypostatic congestion of the lung affects the most dependent parts. Failure of heart-power and dilatation of the pulmonary capillaries are the chief causes of this condition. In states of exhaustion from low fevers, especially typhus and typhoid; after severe surgical operations; in extreme old age; or towards the end of prostrating illness, this failure of heart-power, and consequent stagnation of blood in the lower parts of the lung, usually the bases, is apt to supervene, and is one of the common modes of death. An altered condition of the blood, due to the presence of toxins, is possibly a contributing cause of hypostatic congestion. The site of the congestion is largely influenced by gravitation.

ANATOMICAL CHARACTERS.—Passive hyperæmia almost always affects the bases of both lungs, although often not in an equal degree, the difference depending mainly upon the position of the patient during the last days of life. The affected lung is dark-coloured, and engorged with dark blood. Its tissue is more or less deeply stained with blood, oedematous, and is less crepitant than natural, tearing also more readily than natural under the pressure of the finger. If thoroughly washed, however, in a gentle stream of water, the lung-texture will be found to be but little altered. This condition very readily passes into a low form of pneumonia, and thus portions of the lung may be found consolidated, having much the appearance and consistence on section of a congested spleen (splenification, hypostatic pneumonia). The bronchial tubes and pleura are affected by *post-mortem* staining.

SYMPTOMS.—The symptoms of this form of congestion of the lungs are lividity, especially of the lips and extremities; and quickened shallow breathing; superadded to those of extreme prostration. Dullness on percussion, with enfeebled breathing and moist crepitant *râle*, due to oedema, are found over the bases of both lungs, but in greatest extent on that side to which the patient has been inclining.

TREATMENT.—The treatment consists in vigorously supporting the patient by alcoholic stimulants

frequently administered, and with nutritious food. Nutritive enemata are often of great value. In all exhausting diseases this condition should be anticipated, and warded off if possible by timely support and stimulants, and by frequently turning the patient from one side to the other. Of medicines, ammonia, ether, strychnine, bark, quinine, and oxygen-inhalations are of the greatest value.

Mechanical Congestion.—**ÆTIOLOGY.**—The obstruction may be at the mitral orifice, as in mitral stenosis or regurgitation; or in the left ventricle, when this cavity is dilated and imperfectly emptied, as in the advanced stages of constrictive or regurgitant aortic disease. Whether there be an absolute narrowing of the blood-channel between the pulmonary and systemic circulations—that is, at the mitral orifice or at the commencement of the aorta; or whether, from enlargement of the mitral orifice or from disease or injury of its valve, regurgitation be permitted, so that each contraction of the right ventricle is met and opposed, more or less, by a counter-rush of blood from the left ventricle—in any case, and still more in the combination of two or more of these causes, it is clear that the pulmonary circulation can only go on at an increased pressure by the contraction of the right ventricle becoming more vigorous; and that hyperæmia must result from the damming back of the blood through the pulmonary veins.

Of the causes named, mitral constriction is that which leads most readily to obstructive hyperæmia of the lungs.

ANATOMICAL CHARACTERS.—Obstructive hyperæmia affects the whole of both lungs. The result of the heightened blood-pressure from increased force of injection into the lungs, to overcome an impediment to the escape of blood from them, is most felt in the pulmonary capillaries. These capillaries gradually become lengthened, tortuous, and dilated even to three times their normal dimensions; the fibrous tissue is increased; the thickened and tortuous capillaries intrude upon the air-spaces; and the elasticity of the lungs is diminished. Sometimes minute hæmorrhages take place into the parenchyma of the lung; sometimes larger escapes of blood fill the alveoli of circumscribed patches (*pulmonary apoplexy*). The total result of the intimate changes described is a uniform increase in the size and weight of the lungs, with an increased density and toughness. On section, the lungs are found to be more pigmented and solid-looking than natural, sometimes of a brownish hue (*brown induration*); they are, however, crepitant throughout, except here and there, where they may present fibrous foci or firm, dark, damson-cheese-like patches, fading to brown-red, representing various results and stages of hæmorrhage. There may be some oedema present. The pulmonary arteries and veins are enlarged and congested; and the bronchial mucous membrane is usually the seat of chronic catarrh. Patches of atheroma are frequently to be seen in the larger branches of the pulmonary artery.

SYMPTOMS.—Dyspnoea and cough, both brought on or increased by effort, with palpitation, and oppression or tightness, usually referred to the epigastrium, are the most constant symptoms of obstructive hyperæmia of the lungs. Patients suffering from this condition have repeated attacks of bronchial catarrh, and hæmoptysis is of common occurrence. The hæmoptysis may be considerable, but

more usually the expectoration is streaked with blood or contains small dark coagula.

This form of hyperæmia commonly occurs before middle life, during the usual period of mitral heart-disease. The signs of heart-disease, and most often of constriction of the mitral valve, are present. The subjects of this affection are often undersized and badly nourished: the pigeon-breasted type of chest being common, especially in those cases in which the disease manifests itself early in life. A small, frequent pulse; more or less lividity of lips; and other signs and symptoms of the cardiac disease, of which the pulmonary condition is the consequence, are to be observed. A fine inspiratory crepitant *râle* over the lungs may be heard. During the repeated bronchial catarrhs, with increased pulmonary hyperæmia, to which such patients are especially prone, all symptoms are much aggravated.

DIAGNOSIS.—The existence of obstructive heart-disease suggests the presence of corresponding hyperæmia of the lungs. The fine crepitant *râle* and the hæmorrhagic symptoms and signs more positively point in the same direction.

PROGNOSIS.—The prognosis rests chiefly upon the heart-condition present. Increasing frequency of catarrhal complications, and especially of hæmoptysis, shows the turning of the balance against the patient. The condition may in favourable cases continue for years, especially when dependent upon simple constriction of the mitral valve.

TREATMENT.—The treatment is essentially that of the heart-disease; with the avoidance of all causes which quicken respiration, and which tend to produce catarrhs, to which these patients are so especially prone. R. DOUGLAS POWELL.

LUNGS, Hypertrophy of.—This term is applied to enlargement of the lungs with increased functional power, met with as a compensatory affection of one lung, or of a portion of one lung, to make up for more or less loss of pulmonary tissue by disease.

The dimensions of the enlarged part will be shown by an extension of the normal physical signs. In this way the change can be distinguished from that occurring in emphysema.

LUNGS, Induration of.—See LUNGS, Inflammation of; and Passive Hyperæmia of.

LUNGS, Infarction of.—See LUNGS, Hæmorrhage into.

LUNGS, Infiltrations of.—See PNEUMONIOSIS.

LUNGS, Inflammation of.—SYNON.: Pneumonia; Fr. *Pneumonie*; Ger. *Lungenentzündung*.

DEFINITION.—The term 'pneumonia' has been employed simply to designate inflammation of the lung-tissue. Inflammatory processes in the lungs, however, occur under such diverse circumstances, and are accompanied by such diverse clinical phenomena and histological changes, that 'pneumonia' used in this sense includes widely different diseases.

VARIETIES.—Pneumonias are divisible into the following varieties: A. **Acute Pneumonia**, including *secondary pneumonia*; B. **Broncho-Catarrhal, or Lobular Pneumonia**; and C. **Chronic or Interstitial Pneumonia**. In ad-

dition to these there are those pulmonary inflammations which lead to the formation of *abscess*.

There are certain other forms of lung-consolidation which have sometimes been described as pneumonic, but which are, for the most part, non-inflammatory in their nature, and will, therefore, be only briefly alluded to in the present article. These are: (1) that condition of collapse and hyperæmia, mainly due to weak inspiratory power, feeble circulation, and gravitation, which is so common in the more dependent portions of the lungs in many acute and chronic diseases. (2) Consolidations of the lung resulting from mechanical congestion and embolism, such as are met with in certain diseases of the heart.

The several varieties of pulmonary inflammation must now be considered separately.

Pulmonary abscess is separately described. See LUNG, Abscess of.

A. Acute Pneumonia.—SYNON.: Fr. *Pneumonie Aiguë*; Ger. *Croupöse Pneumonie*.—This is pneumonia *par excellence*. It is sometimes termed *croupous pneumonia*, from the supposed resemblance of the histological process to that of croup. It is also known as *lobar pneumonia*, inasmuch as a large area of the lung is usually involved in the inflammation.

DEFINITION.—Pneumonia may be described generally as an acute infective disease, characterised clinically by sudden onset, severe febrile symptoms, cough, expectoration, and dyspnoea; by the physical signs of pulmonary consolidation; and by a rapid abatement of the general symptoms between the fourth and tenth days. Anatomically it is characterised by an acute inflammation of the lung-tissue, and by the accumulation of the inflammatory products within the alveoli, which products consist, in the main, of a fibrinous exudation and leucocytes.

ÆTIOLOGY.—*Age.*—No age is exempt from pneumonia. It is met with between the ages of one and five years. Here, however, it is liable to be confounded with broncho-pneumonia and with collapse of the lung, so that the results of statistics are less reliable at this than in the subsequent periods of life. It may be stated, notwithstanding, that pneumonia is less common during infancy than has been generally supposed, and that among the pneumonias which are so frequent during this period of life the broncho-catarrhal forms preponderate. After the age of five years the liability to pneumonia diminishes, but it again becomes exceedingly frequent between the ages of twenty and fifty, during which period the liability to the disease reaches its maximum. It is also quite common in old age.

Sex.—In adults more males than females suffer; probably owing to the former being more exposed to atmospheric influences. In early life this difference does not obtain.

Social position, &c.—Pneumonia is more common among the poor and badly fed, and in those whose occupation necessitates an irregular mode of life and great exposure, than among the upper classes of society.

Constitution and health.—Those who are constitutionally weak, and those whose vitality has been impaired by intemperance, insufficient food, anxiety, overstrain, or other causes, are more prone to the disease than the strong and vigorous.

Climatic influences.—Conditions of weather and climate are probably the most important of all known agencies in the causation of pneumonia, and

'catching cold' is the most common exciting cause of the disease. The influence of cold and damp in increasing the liability to acute inflammatory diseases of the chest is well known. This influence is marked in pneumonia, although to a less extent than in bronchitis. Pneumonia is more common in temperate climates than in those regions which are characterised by great heat or extreme cold. Climates and seasons which are liable to sudden changes of temperature, and winds from the north and north-east, appear to be especially favourable to the development of this disease.

Epidemic influences and contagion.—Pneumonia sometimes prevails epidemically; it is occasionally endemic in a house; and evidence tends to show that under certain circumstances, at present unknown, it may be communicated from one person to another. Such facts point to a micro-organism as the causative factor in the production of the disease.

Septic causes.—Sewer-gas emanations appear to play some part in the causation of certain cases of pneumonia. Such cases are said to differ somewhat in type from ordinary pneumonia, and have been termed *pythogenic*.

Previous diseases.—Pneumonia, as is well known, often occurs in those who are the subjects of other disease. It is impossible to speak with certainty as to the relation which subsists between the pneumonia and the disease in the course of which it supervenes. In some cases it may be merely an accidental complication; while in others the previous disease may exercise more or less influence in the causation of the pneumonia (see *Secondary Pneumonia*).

Exciting causes.—In many cases of pneumonia evidence of the existence of any exciting cause is entirely wanting. Of discoverable causes, that which is most common is a sudden chill, or, less frequently, more prolonged exposure to cold or damp. Excluding cold, no conditions can be mentioned which have any marked influence in determining the disease.

BACTERIOLOGY.—Acute lobar pneumonia is an acute specific fever, resulting from the invasion of the lung-tissue by the *Diplococcus pneumoniae*, and its multiplication therein. The organism is present in the exudation filling the lung alveoli, in the sputum, and in the morbid products of such other lesions as may complicate the primary disease, e.g. pleurisy, pericarditis. It is, however, but rarely present in the blood of the general circulation.

Secondary pneumonia is frequently a true lobar pneumonia, presenting the typical appearances of that disease in its acute form, and characterised by the presence of the *Diplococcus pneumoniae* in the exudates. The pneumococcus is present in the saliva of some five or ten per cent. of normal individuals, and it seems probable that in many cases the primary disease simply acts by producing those conditions requisite to enable the saprophytic pneumococcus to invade the lung-tissues of its host and initiate its specific lesions.

Other organisms, such as the *Pneumobacillus* of Friedländer, the *Streptococcus pyogenes longus*, the pyogenic staphylococci, &c., however, act in many cases as the causal agents in the production of the secondary pneumonia, which is then often lobular rather than lobar in type.

The pneumococcus was first isolated by Pasteur in 1880 from the saliva of a case of hydrophobia,

and afterwards from the saliva of healthy individuals. Sternberg demonstrated its presence in the sputa and exudates of cases of pneumonia, although for a long time he was under the impression that the coccus was identical with the organism Friedländer had isolated from similar situations. The honour of pointing out the causal relationship of the coccus to pneumonia belongs to Talamon, while Fraenkel in 1885 completed the chain of evidence necessary to establish the specificity of the pneumococcus.

The *Diplococcus pneumoniae* when observed in sputum, exudation, &c., consists of oval or lanceolate-shaped bodies arranged in pairs or short chains, the individual elements measuring from 0.5 to 0.75 μ in length, and a little less in breadth. Each diplococcus or chain is surrounded by a clear hyaline capsule, composed of a substance closely allied to mucin, which can only be clearly demonstrated by special staining methods. In cultivations of the pneumococcus upon artificial media the cocci are spherical, and although favouring the diplococcus-form frequently occur in chains of varying length, and the capsule is invariably absent. Although under certain conditions the pneumococcus produces resistant forms, these cannot be regarded as true spores.

The pneumococcus is well stained by all the usual aniline dyes, and also by Gram's method (p. 132).

Cultivation.—A really virulent strain of the pneumococcus is only capable of development when cultivated at a temperature approaching that of the body—its range being from 28° C. to 42° C., the optimum 37.5° C.; and then only upon media which are distinctly alkaline to litmus. Its vitality is feeble, cultures in fluid media dying in a few days, those upon solid media in from seven to ten days; upon blood-agar—i.e. nutrient agar upon the slanted surface of which sterile blood has been smeared—however, the coccus will retain its vitality for about two months. The virulence is quickly lost when the organism is cultivated entirely outside the living body.

The pneumococcus grows best upon artificial media when freely supplied with oxygen; it is, however, a facultative anaërobe, and capable of life and growth in an atmosphere devoid of oxygen.

When cultivated in *bouillon* the pneumococcus soon produces a uniform turbidity of the medium; multiplication ceases after 36 or 48 hours, and the medium again becomes clear, owing to the subsidence of the cocci. Growth upon the surface of *agar* appears in 24 hours in the form of delicate transparent spherical colonies resembling minute drops of liquid upon the medium; these later on become more opaque, though they do not increase in size. A smear-culture upon *blood-agar* grows as a thin translucent layer, or as discrete semi-transparent raised colonies, which subsequently become opaque, or take on a buff-coloured tint. Upon the surface of *inspissated blood-serum* the growth occurs in the form of minute jelly-like transparent drops, which in time tend to become greyish-white and opaque. In *litmus-milk* a luxuriant growth takes place, accompanied by the production of an acid reaction, and usually resulting in the coagulation of the casein. No growth takes place upon the surface of potato. Upon gelatine incubated at the room-temperature no growth appears, but if 20 per cent. gelatine is employed and incubated at 37° C. small white

spherical colonies become visible in about 36 hours; these remain discrete, and do not liquefy the medium.

Pathogenesis.—Rabbits and mice are extremely susceptible to experimental inoculation with the *Diplococcus pneumoniae*, whether introduced subcutaneously, intravenously, or into a serous cavity; guinea-pigs are also susceptible, though in a less degree. When highly virulent cultivations are employed death results in from 12 hours to 4 days, from acute septicæmia. *Post mortem*, local reaction is absent or but little marked; with the exception of splenic hypertrophy there are no obvious visceral lesions, but the blood of the general circulation, and of the various organs, is literally crowded with capsulated pneumococci. If less virulent cultures are used the local reaction is more marked, and may consist of extensive fibrinous infiltrations; or pyogenic processes may be initiated, followed, when the subcutaneous tissue is the seat of inoculation, by abscess-formation. After the evacuation of the contents of such an abscess the animal may recover, and will then be found to have acquired a more or less complete immunity towards the pneumococcus.

Cats, rats, sheep, and dogs are highly resistant to experimental infection, and in fatal cases but few cocci are to be detected in the blood-stream; if intrapulmonary injection is practised, pneumonia and pleurisy are produced, and the inoculation is but rarely attended by a fatal result. In so far as his susceptibility to the pneumococcus is concerned, man must be placed in the same category as sheep and dogs.

Fowls and pigeons are immune to the pneumococcus.

ANATOMICAL CHARACTERS.—The changes occurring in the lungs in pneumonia are commonly described as consisting of three stages:—

1. *Stage of engorgement.*—This is the stage of inflammatory hyperæmia and œdema, and it is characterised microscopically by overfulness and slight tortuosity of the pulmonary capillaries, and by swelling of the alveolar epithelium. The lung is of a dark red colour; it is heavier and less crepitant than natural; it pits on pressure; and its cut surface yields a reddish, frothy, tenacious liquid.

2. *Red hepatisation.*—Here there is an exudation of liquor sanguinis and blood-corpuscles. The exuded liquids coagulate within the alveoli and terminal bronchioles, the coagulum enclosing numerous white and a few red blood-corpuscles. The alveolar epithelium is swollen and granular. The lung is now much heavier than in the preceding stage, and is increased in size, so as to be often marked by the ribs. It is quite solid; sinks in water; and cannot be artificially inflated. It is remarkably friable, breaking down with a soft granular fracture. The cut surface has a markedly granular appearance, seen especially when the tissue is torn, and due to the plugs of coagulated exudation-matter which fill the alveoli. The colour is of a dark reddish-brown, often here and there passing into grey. This admixture with grey sometimes gives a marbled appearance. The pleura covering the solid lung always participates more or less in the inflammatory process. It is opaque, hyperæmic, and coated with lymph.

3. *Grey hepatisation.*—This stage is characterised by a continuance of the process of inflammatory

cell-emigration, and by more marked changes in the epithelium. The white blood-corpuscles continue to escape from the vessels, and the alveolar epithelium becomes more swollen and granular. The alveoli thus become more completely filled with young cell-forms, so that the fibrinous exudation is no longer visible as an independent material. The fibrinous exudation now disintegrates, and the young cells rapidly undergo fatty metamorphosis. The alveolar walls themselves, with few exceptions, remain throughout the process unaltered; although very occasionally, when this stage is unusually advanced, they may be found here and there partially destroyed. Owing to these changes, the reddish-brown colour of the lung becomes altered to a greyish or yellowish white. The granular appearance is much less marked; the solid tissue is much softer and more pulpy in consistence; and a puriform liquid exudes from the cut surface of the organ. This stage, when advanced, has been termed 'suppuration or purulent infiltration' of the lung.

Although these three stages of the pneumonic process have been described as succeeding one another in orderly succession, it must be remembered that each stage does not occur simultaneously throughout the whole of the affected area of the lung. The changes advance irregularly, so that while one portion of the lung is in the stage of red hepatisation, another may be in the grey stage—hence the mottled, marbled appearance of the consolidation. The rapidity with which the several stages succeed one another is also subjected to marked variations. In some cases the pneumonic consolidation very rapidly becomes grey, while in others the time occupied in the transition is much longer. These differences will be again alluded to when considering the clinical history of the disease.

Terminations.—The natural and almost invariable termination of the histological process is in *resolution*—the lung gradually returning to its normal condition. This is effected by the fatty and mucoid degeneration, and consequent liquefaction, of the inflammatory products which have accumulated within the alveoli. As the liquefaction proceeds, the circulation in the alveolar walls is gradually restored; the softened products are removed by absorption, and to a much less extent by expectoration; and the lung ultimately regains its normal characters. The other exceptional modes of termination in *gangrene*, *abscess*, and *chronic pneumonia* will be alluded to subsequently.

Site.—The local lesion in pneumonia is in the majority of cases limited to one lung. When double, one lung is usually involved before the other. The right lung is more commonly affected than the left. The part of the lung usually involved is the lower lobe (about 75 per cent.). The consolidation tends to extend upwards and the whole lung may be involved. Pneumonia of the upper lobes is more frequently double than basic disease. It is quite rare for the pneumonic process to commence in two different portions of the lung. When the consolidation is met with in both lungs, or commences in the upper and middle lobes, the pneumonia is often a secondary affection, and has supervened in one whose health has been previously injured, as by alcohol; and such distributions of the local lesion should always make the physician look carefully for evidence of pre-existing disease.

SYMPTOMS.—The incubation-period of pneu-

monia is probably very short. The onset is in the majority of cases sudden, not being accompanied by any premonitory symptoms. Much less frequently, certain premonitory symptoms precede the more severe phenomena which characterise the invasion of the disease. These symptoms include general malaise, headache, chilliness, pains in the back, and loss of appetite.

Invasion.—The invasion in adults is, in most cases, announced by a rigor, much less frequently by vomiting. This rigor is more marked in pneumonia than in almost any other disease. It is usually single, and is rarely repeated, either at the commencement or in the course of the illness. In old subjects the rigor is very frequently absent, and in children its place is often taken by convulsions or vomiting. The rigors or other phenomena marking the invasion of the disease, together with the attendant pyrexia, are usually quickly followed by symptoms pointing to the lung-affection. These symptoms commonly supervene in the course of from twelve to twenty-four hours, although in exceptional cases not until after the lapse of two or three days. The earliest of them are pain in the side, dyspnoea, and cough. These more local symptoms, together with the pyrexia, acceleration of pulse, thirst, and prostration, gradually develop up to the second day of the disease, by which time (and sometimes before this) the pulmonary lesion is usually sufficiently advanced to yield unequivocal physical signs. The general aspect and symptoms of the patient are now tolerably characteristic. The flushed and sometimes dusky face, anxious expression, hurried shallow breathing, hot skin, rapid pulse, short frequent cough, and marked prostration, supervening quickly upon the well-marked initial rigor, indicate pretty clearly the nature of the disease. An herpetic eruption on the lip is very usual and characteristic.

Pain.—The pain in the side, which is increased by deep inspiration and by cough, usually corresponds in situation with that of the affected lung, although it is occasionally experienced in other parts. This symptom may occur coincidently with the rigor, although it more commonly succeeds it. In quite exceptional cases it precedes it, being the first symptom noticed. The pain is due to the implication of the pleura in the inflammatory process; and its severity consequently varies considerably according to the extent and situation of the pulmonary lesion. When this is confined to the central portions of the lung, pain may be entirely absent.

Respiratory phenomena.—Increased frequency of respiration, dyspnoea, and cough, are early and prominent symptoms. The respiration—usually regular—ranges from 30 to 50, and in children reaches even to 70, while the pulse may be only from 90 to 120. This perversion in the pulse-respiration ratio is important in diagnosis. The breathing is shallow; inspiration is abrupt; and, when the pain in the side is severe, respiration is sometimes irregular. The accelerated respiration is accompanied by marked expansion of the *ala nasi*, and by more or less dyspnoea. There is, however, no definite relation between the last-named symptom and the frequency of the respiratory act. Owing to the pain, and to the frequency and difficulty of breathing, speech may be interfered with, and is often rendered exceedingly difficult. Cough is an almost constant symptom, except in the very old. It is short and hacking, rarely paroxysmal like that of bronchitis. It is

usually in the early stages attended by severe pain in the side, so that the patient endeavours to repress it. The cough is usually attended by expectoration; but in children and the old expectoration is often absent, and occasionally such is the case at other periods of life, even throughout the whole course of the illness. The sputa of pneumonia are very characteristic. They are viscid, glairy, and remarkably tenacious, so that they cling to the mouth of the patient, and adhere closely to the sides of the vessel containing them. In colour they present various shades of red, brown, and yellow, owing to the admixture of blood. The appearance so well known as 'rusty' is that most commonly met with. Sometimes they are much more diffuent, and of a dark purple colour, somewhat resembling prune-juice. The characteristic sputa are usually met with on the first or second day of the disease. The amount expectorated is small, and sometimes the pneumonic is associated with a frothy catarrhal sputum. Occasionally a profuse hæmoptysis is an initial symptom. During the period of resolution the sputa become less viscid, and more catarrhal in character, and they usually contain small particles of black pigment. The histological elements met with in the sputa are leucocytes, red blood-cells, pneumococci, and altered epithelium from the alveoli and air-passages; and towards the decline of the disease, fat-granules, pigment, and occasionally fibrinous masses, which are casts of the alveoli and terminal bronchioles.

Pulse.—The pulse in adults usually ranges from 90 to 120, and may be even more frequent. It is commonly much more rapid in children, and less so in the old. In the early stage of the disease it is sometimes full and strong, but soon becomes smaller and easily compressible. It may be irregular, intermittent, or dicrotic. The smallness of the pulse is probably due partly to diminished cardiac power, and partly to the diminished amount of blood which is propelled from the left ventricle, owing to the overloading of the right cardiac cavities which results from the obstructed circulation in the lungs.

Pyrexia.—The pyrexia of pneumonia is continuous, with slight morning remissions and evening exacerbations. The temperature rises very suddenly, with the invasion of the disease, to from 102° to 105° F.; and this high temperature is usually maintained until the period of crisis. This sudden rise and maintenance of a high temperature are very characteristic. The amount of elevation varies in different cases. As a rule, it does not exceed about 104° or 105° F., but temperatures of 107° have been known to terminate favourably. In fatal cases it may reach 109° shortly before death. The maximum temperature is usually met with on the second or third day of the disease, but it occasionally occurs immediately before the crisis. The daily variations are usually as follows: The temperature is lowest about 7 or 8 A.M. In the forenoon, or somewhat later, it commences to rise, and attains its maximum in the early evening. It then falls, but a slight exacerbation occasionally occurs again at midnight, after which it gradually falls. The difference between the highest and lowest temperatures is usually not more than 1° F. The pyrexia runs, for the most part, a uniform course until the period of crisis, when the temperature falls rapidly, in the manner to be hereafter described; but in exceptional cases the course of the fever is more irregular.

Nervous system.—Headache, restlessness, and sleeplessness are almost always prominent symptoms in pneumonia. Slight delirium is also common, especially towards evening, when the pyrexia is at its maximum. Sometimes the delirium is more marked and violent. It constitutes a more prominent symptom in the old, and in the debilitated and intemperate. In drunkards it is constantly present, and here it often assumes the character of delirium tremens. Convulsions are common in children, especially at the period of invasion. They are rare in the adult. These nervous symptoms are sometimes so prominent, especially in drunkards and young children, as to mask the nature of the disease.

Digestive organs.—The symptoms of pneumonia referable to the digestive system are similar to those met with in other severe febrile diseases. There is thirst, with loss of appetite. The tongue is more or less thickly coated with a white fur, and tends in severe cases to become dry and brown. Herpes usually makes its appearance about the lips, and sometimes on other parts, from the second to the fourth day of the disease. Vomiting, which is a common symptom of invasion, is an occasional complication, as is also diarrhoea; constipation, however, is the rule. Sometimes there is slight jaundice.

Urine.—The quantity of urine is considerably diminished, and its specific gravity increased, so that abundant urates are deposited. The excretion of urea is greatly increased, and it may amount to as much as seventy-five grammes in the twenty-four hours. The uric acid is likewise augmented. The inorganic salts, especially the chlorides, are much diminished, and during the height of the disease the chloride of sodium may entirely disappear. This diminution is probably due to abundant exudation of salts into the pneumonic lung. Slight temporary albuminuria is perhaps more common in pneumonia than in almost any other acute febrile affection. The amount is usually in direct proportion to the severity of the disease. Bile-pigment is occasionally met with.

Blood.—The fibrin-elements are increased, and in most cases there is considerable leucocytosis. The leucocytes may be 15,000 to 50,000 per c.mm. This leucocytosis disappears with crisis.

PHYSICAL SIGNS.—The earliest physical signs of pneumonia are usually discoverable within forty-eight hours of the invasion of the disease. They often appear within twelve or twenty-four hours; but occasionally, when the local lesion is deeply seated, nothing abnormal is to be detected until the third or fourth day. It will be well to describe them in the order in which they commonly make their appearance. The time occupied in their evolution will vary according to the rapidity with which the several stages of the pneumonic process succeed one another; and it must be remembered that only some of them are usually observed in practice. In a large number of cases, bronchial breathing and some impaired resonance (the two signs most frequently met with) are the only abnormal signs discoverable.

The earliest abnormal physical signs are due to the pain caused by the movement of the affected side; to the hyperæmia of the pulmonary capillaries; and to the commencing exudation into the air-vesicles. The respiratory movements of the side are more or less impaired. This is partly owing to pain, and partly to diminished elasticity of

the lung-tissue. The breath-sounds are usually somewhat weak and harsh, but not distant; although, as stated by Stokes, they are occasionally in the earliest stage harsher and louder than natural. Percussion during this stage is usually not markedly altered. The resonance, however, in the upper portions of the chest is sometimes appreciably tympanitic in quality. The vocal fremitus is increased. The most important sign, however, of the congestive stage is *fine crepitation*. This râle consists of a number of fine, dry, crackling sounds, following one another in rapid succession, which were aptly compared by the late C. J. B. Williams to the sounds produced by rubbing the hair between the fingers close to the ear. It occurs during the later period of this stage, when the process of exudation from the pulmonary capillaries is commencing to take place. This râle is inspiratory; it is intensified by deep inspiration and also by cough, and it is sometimes necessary to make the patient cough in order to elicit it. A similar râle is often heard with deep inspiration in portions of the lung which have been imperfectly expanded. Such imperfect expansion is common in the posterior parts of the lungs of patients who have been confined to bed from acute or chronic disease, and in whom, owing to muscular weakness, inspiration is incompletely performed. The râle produced under these circumstances is distinguished from pneumonic crepitation inasmuch as it completely disappears after a few deep inspirations; whereas the pneumonic râle, when once established, persists until the consolidation of the lung is tolerably complete.

The physical signs of the stage of hepatisation are due to the more or less complete consolidation of the lung. The fine crepitation which characterised the later periods of the preceding stage may continue during the process of consolidation, but ceases as the filling of the air-vesicles becomes complete; although it may often still be heard at the confines of the more firmly consolidated lung. It frequently happens, however, when the consolidation is rapidly induced, that no crepitation is heard throughout the course of the disease until the period of resolution. The situation of the cardiac impulse is not altered. Vocal fremitus, when obtainable, is usually increased. To this general rule, however, there are exceptions, and it not infrequently happens that it is unaltered, and it may even be completely absent. This diminution in the vocal fremitus is sometimes due to the blocking of the smaller bronchi with the inflammatory exudation, but more frequently it appears to result from an accumulation of mucus. In the latter case it may sometimes be restored by cough. Coincidentally with the increase of vocal fremitus there is usually increased vocal resonance, and sometimes whispering pectoriloquy. The percussion-sound now is much more deficient in tone, and there is also an increase in the sense of resistance, but neither the dulness nor the resistance is so marked as in pleural effusion. In basic disease, percussion under the clavicle often yields a distinctly amphoric note, while the lower portions of the chest may be almost absolutely dull. The auscultatory sign of this stage is bronchial breathing. This is usually remarkably superficial, high-pitched, and metallic in quality (tubular breathing). Sometimes, however, it is less metallic and softer (diffused blowing—Walshe). These respiratory phenomena, like the vocal resonance and fremitus,

may be absent over larger or smaller areas of the consolidated lung, owing to the obstruction of the bronchi by catarrhal secretion. The slight pleurisy which constantly accompanies the pneumonia is rarely susceptible of physical demonstration during this stage. This is probably owing to the immobility of the solid lung. During the period of resolution, as expansive power returns, friction-sounds are occasionally audible.

Resolution usually commences in those portions of the lung which were the last to become consolidated. The most important and the earliest of the signs of resolution is the return of crepitation. The crepitation, however, differs from that met with in the earlier stages of the disease. It is larger, coarser, and more liquid in character—*redux crepitation*; and its liquid character gradually increases until it may become distinctly bubbling. When resolution is very rapid, *redux crepitation* may be absent. The bronchial breathing now loses its metallic ringing quality; the percussion-dulness gradually disappears; and the respiration regains to a great extent its normal characters.

The commencement of resolution and of the improvement in the physical signs occasionally takes place coincidently with the establishment of crisis; but more commonly it is not observed until from twenty-four to forty-eight hours after the temperature has reached the normal standard. The time occupied in the completion of resolution varies. Sometimes all physical signs almost completely disappear in twenty-four hours. Usually, however, resolution is less rapid, and marked signs of consolidation remain for periods varying from two or three days to two weeks. A slight amount of dulness and some weakness of respiration often persist at the posterior and inferior portions of the lung for even still longer periods. This is especially the case if the pneumonia is complicated with pleurisy. When marked signs of consolidation exist after the third week, there always exists more or less probability that the pneumonic process may become chronic.

COURSE AND TERMINATIONS.—The symptoms which have been described continue with often increasing severity up to about the end of the first week, sometimes longer, when there is usually an abrupt subsidence of the pyrexia—*crisis*, and the disease generally terminates in *recovery*. In other cases *death* occurs either before or after the crisis. The disease may also terminate in *gangrene* of the lung; in *pulmonary abscess*; or in *chronic pneumonia*. These several modes of termination must be considered separately.

Complete recovery.—This is the most common termination of pneumonia in young and healthy adults, and the improvement usually begins with the *crisis*. The time at which this crisis takes place, as indicated by the sudden fall of temperature, varies from the third to the twelfth day. In the majority of cases it is on the fifth, sixth, or seventh day; occasionally as early as the third day; and sometimes it is prolonged into the middle of the second week.

Crisis is the most characteristic feature of pneumonia. Its supervention is sometimes indicated by a change in the pulse, which becomes softer, and somewhat irregular in force and rhythm. The most marked phenomenon attending it is the abrupt fall of the body-temperature. This fall usually begins late in the afternoon or evening; and the

temperature very often reaches the normal standard in from sixteen to twenty-four hours. Sometimes the fall is even more rapid—in from five to ten hours. The morning remission and evening exacerbation occur during the period of defervescence. The temperature not infrequently falls 1° or 2° F. below normal, and may remain so for two or three days. Occasionally a marked increase in the pyrexia is observed immediately before the commencement of defervescence.

With the fall of temperature all the symptoms rapidly improve. The skin becomes moist and often perspires profusely. The amount of urine increases. The respiration falls in frequency; and, to a less extent, the pulse. The cough becomes looser, and the expectoration more copious. The sputa gradually lose their tenacity and rusty colour, and become more bronchitic in character; they are now usually mingled with more or less black pigment. An improvement in the physical signs is sometimes observed at the same time; more commonly, however, this does not take place till one or two days later. The patient often falls into a deep sleep, and on waking, with the exception of great weakness, declares himself pretty well, and begins to ask for food. In some cases, however, the amount of prostration following the crisis is so great that the return to health is more gradual; and a condition of collapse may ensue, which often terminates in death. There is a liability to diarrhoea at this period which it is all-important to bear in mind.

In the majority of cases pneumonia terminates abruptly in the manner above described. Sometimes, however, the temperature falls more gradually—by *lysis*; and recovery is more protracted. Defervescence may not be complete till the end of the second week. The critical fall of temperature is occasionally interrupted by more or less marked exacerbations, due either to the implication of fresh portions of the lung, or to the supervention of one of the complications to be hereafter alluded to.

In some cases, after the occurrence of crisis, there is a slight return of fever of a hectic type. This irregular fever may last three or four days. Its persistence should always suggest a pleural complication (see **COMPLICATIONS**, p. 924). Lastly, a distinct relapse may occur; but this is very rare, and the relapse is in most cases shorter and less severe than the primary attack.

Death.—When pneumonia terminates fatally, it usually does so towards the end of the first, or quite at the beginning of the second week, and often *after crisis*. The great fatality of the disease is mainly due to the attendant toxæmia; hence cardiac failure is a much more important danger than apnoea. The danger from direct interference with the respiratory function increases with the extent of lung involved, and it is consequently greater in double than in unilateral disease. Failure of cardiac power is undoubtedly the most important element of danger. There are several conditions in the disease which tend to interfere with the circulation. First and foremost of these is the toxæmia. This, which at present we have no means of combating, is often intense; and the consequent interference with metabolism and damage to tissue is increased by the accompanying high body-temperature. Then, again, the obstruction to the circulation in the lung by throwing increased work on the right heart augments the difficulty.

Such being the modes by which pneumonia tends to destroy life, it will be readily understood that the earliest and most important signs of unfavourable augury are on the side of the circulation. The pulse becomes more frequent, small, irregular, and often dicrotic. The frequency of the respiration, the dyspnoea, and the cyanosis increase. The cough becomes feeble and ineffectual. Owing to the engorgement and failure of power of the right ventricle, general pulmonary oedema usually supervenes, so that moist *râles* are audible at both bases. The extremities become cold, and there is often profuse perspiration. The mind wanders, and a condition of partial coma supervenes before the close. In some cases a rapid rise of temperature takes place before the fatal termination, while in others there may be a considerable fall in the thermometer. In those exceptional cases in which pneumonia tends to become more or less chronic, death may occur during the third or fourth week. Death may also result from the complications.

Gangrene.—This is quite rare. It is most common in chronic drunkards, and in those of debilitated constitution. Its occurrence appears to be due partly to blocking of vessels, and partly to the local influence of some special form of septic infection. It is usually limited to a small area of the pneumonic lung; and is either diffuse or circumscribed. It commonly supervenes late in the disease; and the most reliable signs of its occurrence are marked foetor of the breath and the expectoration, and great prostration. Portions of lung-tissue are occasionally found in the sputa. Gangrene is almost invariably, but not necessarily, fatal. *See* LUNGS, Gangrene of.

Abscess.—This is also very rare. *See* LUNGS, Abscess of.

Chronic Pneumonia.—Acute pneumonia in very exceptional cases becomes chronic, and leads to induration of the lung. *See* CHRONIC PNEUMONIA.

VARIETIES.—The clinical phenomena of pneumonia are occasionally somewhat different from those which have been described. Variations are met with resulting from differences in the individual, and in the ætiological factors concerned in the disease.

In the aged pneumonia sometimes runs a latent course. Invasion may be unattended by rigor or other prominent symptoms. The elevation of temperature is much less than in adults. Cough, expectoration, pain, and dyspnoea may be completely wanting. If cough be present, the sputa often do not present the rusty tinge, but are simply transparent or muco-purulent. Slight pyrexia, with some increased frequency of breathing and prostration, may be the only symptoms present. This latent course of pneumonia it is important to bear in mind, as it indicates the necessity of making a most careful physical examination of the chest in all febrile illnesses of the aged.

In young children the disease more frequently affects the upper lobe (apical pneumonia); and nervous symptoms are often obtrusive, simulating meningitis. When pneumonia occurs in those who are debilitated by previous disease, by the abuse of alcohol, or by other causes, the phenomena of invasion are usually not pronounced, and symptoms of intense prostration may occur early. The initial rigor and pain in the side are often observed; but cough is slight, and the expectoration, instead of the rusty-brown tint, may present a dirty-brown or

prune-juice appearance. Various symptoms of an asthenic type soon become prominent; the most important of which are low delirium, alternating with stupor; tremors; and paralysis of the sphincters. The tongue is brown and dry; sordes form on the teeth; the pulse is exceedingly rapid and feeble; and there are often slight jaundice and albuminuria. Death usually supervenes some time during the second week of the disease. After death the lung is usually found to be less firmly consolidated and less granular than in sthenic forms of pneumonia; and the stage of grey hepatisation in some cases is exceedingly advanced.

Secondary Pneumonia.—Pneumonia occurring in the course of other diseases usually differs somewhat from the primary disease. The changes in the lung may be precisely similar, but in many cases the consolidation is less dense and fibrinous, and epithelial changes constitute a more or less prominent feature. Secondary pneumonia occurs chiefly in the acute specific fevers—typhoid and influenza; in acute rheumatism, Bright's disease, and in many other acute and chronic diseases. It is a frequent terminal event in many diseases.

The symptoms are usually less pronounced than in primary pneumonia, and they are often masked by those of the pre-existing disease. Latency may be so marked that the pneumonia is overlooked, and its recognition in most cases depends upon careful examination of the lungs.

Hypostatic Pneumonia.—Allusion may be made here to the consolidations so often met with at the bases and more dependent portions of the lungs in the course of both acute and chronic disease, which are due mainly to mechanical causes, and have been termed *hypostatic pneumonia*. They consist, in the main, of collapse, hyperæmia, and oedema of the lung-tissue, resulting from weak inspiratory power, feeble circulation, and gravitation. The consolidation thus mechanically induced is increased by exudation from the vessels due to the damage to their walls caused by the blood-stasis. The diagnosis between this consolidation and a secondary pneumonia is sometimes impossible.

COMPLICATIONS.—The complications of pneumonia are, for the most part, due to the invasion of other tissues than the lung by the *Diplococcus pneumoniae*.

Pleurisy.—Pleurisy of slight intensity, and unaccompanied by effusion, is, as already stated, almost invariably met with in pneumonia over those portions of the lung which are consolidated. This is natural to the disease, and cannot be regarded as a complication. Pleurisy of greater intensity, and attended by a sero-fibrinous effusion, occurs in from 5 to 15 per cent. of the cases (*pleuro-pneumonia*). Signs of effusion are not usually discoverable before the third or fourth day of the disease. The amount of liquid varies with the extent of the lung-consolidation. When this is considerable, involving nearly the whole lung, there is but little room for effusion. The supervention of such pleurisy does not commonly materially modify the course of the disease. It may, however, protract the period of defervescence. Its influence in interfering with the disappearance of the physical signs has been already alluded to.

Empyema.—A suppurative pleurisy, occurring usually at the termination of the disease, often after crisis, is not infrequent; and a persistence or recurrence of the pyrexia should always suggest it.

Bronchitis.—This is also a common complication, especially in the aged and in young children. Many cases, however, which have been described as pneumonia, associated with bronchitis, have doubtless been cases of broncho-pneumonia. The bronchitis almost invariably affects both lungs. Its supervenition is attended by an increase in the cough and in the amount of expectoration. When it involves the smaller tubes it constitutes a serious complication.

Pericarditis.—This is not uncommon. It may result from the direct extension of the inflammatory process from the pleura. When extensive, it is a grave complication, and greatly increases the mortality.

Endocarditis.—This occasionally occurs. Osler found it in 10 per cent. of his cases.

Meningitis.—This is a rare complication. It appears in most cases to be caused by the pneumococcus.

Jaundice.—A slight yellowish tinge of the conjunctiva, and even of the skin, is not infrequent in pneumonia, and has no clinical significance. Much more extensive jaundice is also occasionally met with, which appears usually to be due to duodenal catarrh, and is attended by gastric symptoms; a non-obstructive jaundice sometimes occurs.

Relapse in pneumonia is exceedingly rare. Recurrence after an interval of months or years is more common than in any other acute disease except erysipelas.

DIAGNOSIS.—The diagnosis of pneumonia, usually easy, is sometimes attended with difficulty. Although it cannot be made with absolute certainty prior to the appearance of physical signs of pulmonary consolidation, in the majority of cases a very confident opinion can be formed as to the nature of the illness in the earliest stages, before such signs are discoverable. The phenomena which are of the most diagnostic value at this early stage of the disease are the pyrexia, the increased frequency of respiration, the altered pulse-respiration ratio, the pain in the side, and the cough. The sudden and rapid rise of the body-temperature, which usually reaches its maximum in forty-eight hours, is very characteristic; such a rapid attainment and maintenance of a high temperature being more common in pneumonia than in any other disease. When physical signs of pulmonary consolidation are discoverable, which they usually are within forty-eight hours, the diagnosis becomes certain.

Difficulties in diagnosis may arise in those cases in which the local process in its earlier stages is deeply seated. Here characteristic physical signs may be wanting for four or five days, during which time some doubt may exist as to the nature of the disease. In the aged the disease so often runs a latent course that its existence may be easily overlooked unless a careful examination be made of the chest. Then, again, in the intemperate its nature may be masked by delirium and other nervous symptoms.

In children, apical pneumonia with cerebral symptoms may simulate meningitis; and a pleuritic effusion, owing to the frequent prominence of bronchial breathing, may be mistaken for pneumonic consolidation.

The diagnosis of *secondary* pneumonia occasionally presents some difficulty. Owing to the frequent absence of marked symptoms the disease may be readily overlooked unless careful examination is made of the lungs.

The diagnosis of pneumonia from other diseases

of the lungs is rarely difficult. The disease with which it is most liable to be confounded is pleurisy; and when a pleural effusion complicates pneumonia, some care may be required to avoid error. That somewhat rare variety of acute pulmonary tuberculosis, in which a large area of lung becomes rapidly consolidated, may be mistaken for pneumonia. Here, however, although the whole lung may be involved, the disease usually commences in the upper lobes, so that the abnormal physical signs are more marked at the apex. The onset of the disease also is commonly much less sudden, and its course is more protracted. Examination of the sputum for tubercle-bacilli may, however, be necessary to establish diagnosis. It may be stated generally that, in all acute consolidations of the lung, a protracted course of the pyrexia, and the occurrence of marked exacerbations and of remissions of the fever at irregular intervals, afford grounds for the supposition that the consolidation is tubercular.

The diagnosis of pneumonia from broncho-pneumonia and collapse of the lung will be considered when treating of broncho-pneumonia. See Broncho-Pneumonia, p. 930.

PROGNOSIS.—Pneumonia is one of the most fatal of the acute diseases, and in few is it more difficult to make a reliable forecast. The danger is due mainly to the attendant toxæmia, much less to the extent of lung affected.

Of all the circumstances which influence prognosis, that which is perhaps the most important is the state of the general health. In those whose vitality has been damaged by previous disease, by the abuse of alcohol, by privation, or by mode of life, pneumonia is exceedingly dangerous. The prognosis is, however, especially grave in those injured by the long-continued abuse of alcohol. Pneumonia occurring in those who are the subjects of pre-existing disease—*secondary* pneumonia—is more dangerous than primary; and that occurring in chronic Bright's disease is especially fatal.

Of equal importance is the age. In healthy children the mortality from pneumonia is comparatively small. The fatality formerly ascribed to the disease at this period of life was probably owing in great measure to the inclusion of cases of broncho-pneumonia in the statistics; the latter disease being exceedingly fatal. Healthy young adults rarely die; after the age of thirty the mortality increases considerably; and in the old pneumonia is an exceedingly fatal disease.

Pneumonia is more fatal in females than in males, the mortality being in the proportion of three to two. Pregnancy renders the disease more dangerous.

The danger of pneumonia increases somewhat with the extent of lung involved. It is, however, the implication of both lungs which renders the prognosis especially grave. With regard to the situation of the consolidation, it may, perhaps, be stated generally that pneumonia commencing in the upper lobes is rather more serious than basic disease. This difference does not obtain in the case of children. The gradual extension of the consolidation late in the disease, and the spreading of the inflammatory process from one centre to another, constitute elements of gravity. When resolution is much protracted, the fact that the disease in very exceptional cases terminates in an indurative consolidation of the lung is not to be forgotten.

The mortality of pneumonia is greatly increased by the existence of complications. The prognostic importance of these has already been considered.

Of symptoms, the most important are those indicating failure of the circulation. A pulse which in the adult is persistently over 120, and in the child over 140, is of grave significance. Marked irregularity in force and rhythm is also unfavourable, especially in the young. Weakness of the first sound of the heart is another indication of failure. Variations in the respiration are of less import. Extreme quickness of breathing, marked dyspnoea, and cyanosis are not uncommon in cases which terminate in recovery; at the same time, such symptoms must have more or less unfavourable significance. Sputa of a dark prune-juice colour are of somewhat evil augury; as is also an abundant liquid puriform expectoration. The indications derived from the pyrexia are of less prognostic value in pneumonia than in most acute diseases. A temperature of 105° or 106° F. does not in itself indicate danger. Greater elevation is grave. In many fatal cases the temperature never attains 102°. The significance of a protracted defervescence has already been alluded to. On the side of the nervous system, it is to be remembered that slight delirium is not uncommon; but when it is marked, and especially when it occurs late in the disease and prevents sleep, it is most grave. It is of greater significance in adults than in children. Tremors and a tendency to coma are also unfavourable. A dry, brown tongue is unfavourable, especially when associated with only a moderate degree of pyrexia. Gastric catarrh and diarrhoea add to the danger; and the liability to diarrhoea at the period of crisis, and the frequency with which it then endangers life, should be ever remembered. Tympanites is very unfavourable. A slight amount of jaundice is not of ill omen, but the appearance of much albumen in the urine early in the disease is undoubtedly of bad import.

TREATMENT.—In considering the treatment of pneumonia, it is of the utmost importance to bear in mind the true nature of the disease. All rational and successful therapeutics must be based upon the recognition of the fact that it is not simply a local affection of the lung which we wish to influence. The 'heroic' methods of treatment by venesection, tartar emetic, &c., so much in vogue in the past, had for their object the controlling or cutting short of a simple pulmonary inflammation. Such methods have now been abandoned, and with our increasing knowledge of the bacteriology of the disease we are looking with confidence to the discovery of specific remedies which may secure immunity or successfully combat the local inflammation and the attendant toxæmia. An anti-pneumococcus serum is already being used with results that justify further trial. Washbourn recommends the injection of 20 c.c. of this serum twice daily. See SERUM-THERAPEUTICS.

Failing specific remedies our object must be, as in other specific fevers, to conduct the disease to a favourable termination. If we cannot arrest its progress, we can often do very much both to maintain the strength of the patient, and to modify those elements in the disease which tend to destroy life.

The modes by which pneumonia tends to destroy life have been already considered—that damage to the tissues generally which obtains in all acute specific diseases; and direct interference with the

respiratory function due to the lung-consolidation. Of these, the former is the more important, and impaired cardiac power is its most serious consequence. The natural course of the disease is also to be remembered. In the strong and robust, pneumonia usually terminates in recovery. It is in those who are debilitated by age, privation, mode of life, abuse of alcohol, or pre-existing disease, that such great mortality attends it. It is a question of the intensity of the disease on the one hand, and of the resisting power of the individual on the other. Such considerations as these indicate the importance not only of doing all that is possible to husband and support the strength of the patient, but also of not interfering too actively with the disease, unless circumstances arise which, if uninfluenced by treatment, would tend to prove rapidly fatal.

Such being the general principles which should guide us in the treatment of pneumonia, the manner in which they are to be best carried out may now be indicated.

Everything should be done to husband the strength of the patient, and the services of efficient nurses are all-important towards the attainment of this object. Perfect rest must be enjoined, and all unnecessary speaking be forbidden. The patient should be kept in bed, be lightly covered, and be sponged freely three or four times daily with cold or tepid water. The room should be large and airy; and the temperature about 60° to 62° F. It should be well ventilated: a plentiful supply of fresh air is most important, and, although due care should be exercised in the ventilation, there is not the same necessity to keep the patient scrupulously protected from draughts as in the treatment of acute bronchitis.

The diet should be carefully regulated, nutritious and easily digestible, consisting of milk, milk with egg, beef-tea, mutton- or chicken-broth, meat-essences, and similar articles, given in varying quantities and at varying intervals, according to the condition of the patient. Water should be allowed liberally to relieve thirst and promote perspiration. With the object of stimulating the secretion of saliva and promoting the appetite, it is well to keep the mouth cleansed with glycerine and lemon-juice. Some acid and bitter drink, as one made with hydrochloric acid and orange-peel, may also be given.

In the earliest stage of the disease it is usually wise to give a small dose of calomel, or of blue pill and colocynth, to be followed in five or six hours by a saline aperient. The exhibition of purgatives, however, requires great care, as they occasionally set up a catarrhal condition of the intestine, and consequent diarrhoea, which may prove an element of danger, especially near the period of crisis. It is important, therefore, except on the first day of the illness, to procure all necessary evacuation of the bowels, by a small dose either of castor oil, or of colocynth and hyoscyamus, or by simple enemata. With the object of promoting elimination by the skin and kidneys, some citrate or acetate of ammonia with citrate of potassium should be given three or four times daily.

On the first day of the disease when the symptoms of invasion are accompanied by much pain, anxiety, and restlessness, morphine used with care and judgment is often of the utmost value. Morphine ($\frac{1}{4}$ grain with, if necessary, strychnine $\frac{1}{30}$ grain) may be given hypodermically.

There are two circumstances which often tend greatly to interfere with the satisfactory progress of pneumonia—the pain in the side, and sleeplessness. Pain in the side is often troublesome during the first two days. It may usually be relieved by the application of large hot linseed poultices, or hot fomentations, or by the use of an ice-bag. If these means do not succeed, a small blister (2 by 2 inches), or three or four leeches, may be applied to the seat of the pain, and the hot applications then renewed. In exceptional cases small doses of morphine hypodermically may be necessary to relieve this symptom. Cough is only harmful by increasing the pain, and rarely calls for interference. Sleeplessness is always a more or less troublesome symptom, and yet to secure a sufficient amount of sleep is obviously of primary importance. A careful nurse, keeping the room quiet and darkened, and attending to the comfort of the patient; the relief of pain by the measures above indicated; and sponging with tepid water the last thing at night, are often sufficient to secure some interrupted sleep. Should it be necessary, some hypnotic must be given: bromide of potassium and hyoscyamus, sulphonal, chloralamide, Tinct. Chloroformi et Morphinæ Co., are all useful, and, if they fail, morphine guarded by atropine and strychnine may be administered *sub cutem*. Chloral hydrate is usually contra-indicated, on account of its depressing effect upon the circulation.

A large number of cases of pneumonia terminate in health without the necessity of any further interference on the part of the physician than has been described. Frequently, on the other hand, circumstances arise indicative of danger, which require to be met by more active treatment.

Pyrexia is sometimes excessive, but in attempting to interfere with it, it must be remembered that it is natural to the disease, and only when excessive does it become harmful. A temperature of 104° is, in itself, of no unfavourable import. Frequent sponging with tepid or cold water, by cooling the patient, and promoting rest and sleep, is always desirable. The frequent, or more or less continuous, application of an ice-bag to the affected side, as recommended by Lees, is another means of refrigeration often useful. According to this physician it controls not only the temperature but also the lung-inflammation. It usually relieves pain and increases comfort. If the patient likes it, it is wise to make use of it. In children, an ice-poultice is preferable to the bag.

Hyperpyrexia is occasionally met with. A temperature of 105° calls for a more assiduous employment of the refrigerating treatment already alluded to; and in those exceptional cases in which the temperature reaches 106° or 107° a cold bath at 75° or 80° may be necessary. Antipyretic drugs are dangerous in pneumonia; but quinine in 5-grain doses, given in cachets, is sometimes of undoubted use, although it may not materially influence the temperature-chart. High temperature in pneumonia always calls for the free exhibition of alcohol.

Symptoms indicative of danger are especially likely to arise in those whose vitality is impaired by age, habits, or other causes, and, in such, special care and watchfulness should be exercised in anticipation of any unfavourable symptom. The chief source of danger, as already stated, is failure of cardiac power, and consequently all symptoms of such failure must be carefully watched for.

Any sign of cardiac failure will in the first place suggest the advisability of administering alcohol. It may be stated generally that a pulse of over 120 calls for the employment of stimulants. Brandy appears in most cases to answer best. The amount administered must depend upon its effects; and although in most cases from four to eight ounces in the twenty-four hours will be sufficient, if the asthenia persist it may be given in larger quantities. The disease is one of comparatively short duration, and there is perhaps no other acute illness in which the free exhibition of alcohol, when indicated, is more likely to be advantageous.

The free inhalation of oxygen is also desirable under these circumstances. It not only relieves the embarrassed respiration, but tends to prevent heart-failure. Oxygen should always be available in a severe case, and it should be used early. It sometimes also promotes sleep, which in these cases is obviously of primary importance.

Of drugs, the most useful is strychnine. This is best given in full doses at rather long intervals—liq. strych. hydrochlor. m iij to v , by the mouth or hypodermically every six or eight hours. Ammonium carbonate in full doses (gr. v to gr. x) is also useful. Digitalis, although indicated by a rapid and failing heart, is of doubtful value.

The special danger at, and immediately after, crisis calls for the assiduous employment of the above treatment at this period, and indicates the importance of not relinquishing it too soon after the critical fall of temperature.

Interference with respiration from extensive consolidation of the lung is too often an important source of danger; and the consequent increased work thrown on the right ventricle tends to increase the heart-weakness. Symptoms of cardiac are thus usually associated with those of respiratory failure; and in dealing with the latter, we must depend mainly upon the means already described as best calculated to help the heart. The free use of strychnine and oxygen, which stimulate not only the heart but the respiratory centre, may often avert death.

Venesection is well known to relieve the dyspnoea of pneumonia. It diminishes the pulmonary congestion and unloads the distended right heart. It must, however, be borne in mind that the relief is merely temporary, and that the loss of blood must tend more or less to weaken the patient, and hence to favour that condition of asthenia which is of all things the most to be feared. Bleeding is certainly only to be thought of when in the *early* stage of the illness the dyspnoea is urgent, and when at the same time the pulse is strong and full; and it should not exceed the removal of eight or ten ounces of blood. Such cases are certainly not common.

Of the complications, delirium sometimes calls for treatment. Active delirium is not common in pneumonia, except in those who have been intemperate. When marked, it is always indicative of danger. In its management the practitioner must be guided by the general condition of the patient; but, speaking generally, it calls for the free exhibition of alcohol, and the external application of cold. Cold, applied in some of the ways already indicated, is of especial value in these cases, not only reducing the temperature, but quieting the patient and often producing refreshing sleep. The influence of an experienced nurse is all-important. Bromides are often useful, and it may be necessary

to give morphine hypodermically. Hyoscine ($\frac{1}{200}$ grain) may be used with caution (p. 707).

Of the management of other complications occurring in the course of pneumonia there is nothing special to be remarked; they must be treated on general principles. The existence of bronchial catarrh often requires small doses of ipecacuanha with carbonate of ammonium and salines. Diarrhoea and gastric symptoms are to be met by careful dieting, chalk, bismuth, and, if necessary, other astringent remedies. In pneumonia, as in other acute diseases, the administration of an opiate enema is an efficient and safe means of checking diarrhoea. Pericarditis rarely admits of any special interference. The persistence of pyrexia or its recurrence after crisis may call for exploration of the pleura, and an empyema may require treatment. See PLEURA, Diseases of.

Convalescence.—During the period which immediately succeeds the crisis, the utmost care is required to support the patient, and to prevent any serious amount of prostration, which at this time so often supervenes. Stimulants are usually required for some days after the temperature has attained the normal standard. Convalescence in most cases is quickly established. Solid diet is soon desired, and may be safely given. Tonics—such as quinine, iron, and cod-liver oil—and change of air are useful in assisting the restoration to health.

B. Broncho-Pneumonia.—**SYNON.**: Catarrhal Pneumonia; Lobular Pneumonia; Fr. *Pneumonie Lobulaire*; *Broncho-pneumonie*; Ger. *Bronchopneumonie*.

DEFINITION.—Broncho-, catarrhal, or lobular pneumonia is inflammation of the lung, due to an irritant entering and spreading by the bronchi. The irritant usually causes, in the first place, inflammation of the bronchial mucous membrane, which spreads to the bronchioles and alveoli. This frequent association of the pulmonary inflammation with bronchial catarrh explains the terms *broncho- and catarrhal*, which are applied to this form of pneumonia. The pulmonary inflammation is commonly limited to scattered groups of air-vesicles (*lobular*), but sometimes it causes large areas of consolidation (*lobar*). The inflammatory products which fill the alveoli consist principally of cells, derived from the epithelium of the alveoli, and from the bronchial mucous membrane; exudation and emigration play a much less prominent part than in ordinary pneumonia.

ETIOLOGY.—The most important group of cases of broncho-pneumonia are those associated with a more or less general bronchitis, the bronchial usually preceding the pulmonary inflammation. Whatever causes inflammation of the bronchial mucous membrane may be a cause of broncho-pneumonia, and when the inflammation involves the smallest bronchi, its extension to some of the alveoli is almost invariable.

Simple non-specific bronchitis is frequently followed by broncho-pneumonia, especially in childhood and in old age. All those conditions which favour the occurrence of such bronchitis must therefore be enumerated among the causes of this form of pneumonia. Of these conditions it will be sufficient to mention here the marked influence of cold and damp. It is, however, the specific forms of bronchitis, associated with measles, whooping-cough, diphtheria, and influenza, which are the most liable to be followed by broncho-pneumonia.

It occurs less frequently in scarlatina, small-pox, and typhoid fever.

All conditions which tend to impair the general health and strength favour the occurrence of broncho-pneumonia. The weakly and debilitated suffer most. Bad air, insufficient food, and rickets are important predisposing causes.

Broncho-pneumonia is most common during the first four years of life—the period when bronchial catarrh, measles, and whooping-cough are so frequent. It is also common in old age. In young adults it is comparatively rare. Sex has no influence.

Another group of cases of broncho-pneumonia are those due to the inhalation of more definite irritants (aspiration-pneumonia): (1) dust, particles of steel, iron, stone, coal, &c., gaining access to the air-passages may cause inflammation of the bronchi and subsequently of the alveoli; (2) irritant gases, e.g. ether-pneumonia; (3) micro-organisms. Under this head the bacillus of tuberculosis is the most important—a tubercular broncho-pneumonia being the principal lesion in chronic pulmonary tuberculosis. Septic blood and pus may be sucked into the air-passages in diseases of, or during operations on, the nose, mouth, pharynx, and trachea. The contents of an empyema or of a bronchiectatic cavity may be aspirated; as may also blood after a pulmonary hemorrhage. Lastly, septic organisms conveyed with particles of food or saliva may enter the air-passages when the glottis is insensitive or paralysed. The pneumonia in these cases is usually more localised than in the preceding group, and there is less attendant general bronchitis. When the irritant is septic, suppuration and even gangrene are liable to occur.

BACTERIOLOGY.—To enumerate the micro-organisms that at various times have been regarded as specific for this condition would be to catalogue the pathogenic bacteria, including pathogenic moulds. In point of fact no one organism has been found associated with broncho-pneumonia with sufficient constancy to warrant belief in its specificity, but, on the contrary, it would appear that the invasion of the lung-tissue by any one or more of the pathogenic bacteria may, under certain conditions as yet but little understood, result in the production of the disease.

The organisms most frequently associated with this condition are certainly the pyogenic streptococci and staphylococci, and the pneumobacillus.

ANATOMICAL CHARACTERS.—The appearances presented by the lungs after death from broncho-pneumonia vary. The bronchi always exhibit signs of more or less bronchial catarrh. This may involve the whole of the bronchial mucous membrane, but it is usually most marked in the smaller tubes. These are found containing a thick, tenacious, and often puriform secretion, which is occasionally here and there drier or inspissated. The mucous membrane of these tubes is more or less softened, swollen, red, and thickened, and often presents irregular superficial erosions. Owing to this inflammatory swelling the tubes stand out prominently on section of the lung. Cylindrical dilatations of the tubes are also frequently met with.

The lung-tissue itself exhibits, associated in various degrees, collapse, congestion, œdema, emphysema, and pneumonic consolidation. The bluish, non-crepitant, smooth, depressed portions of col-

lapse, which become darker and more friable with age, are usually most abundant in the lower lobes and margins of the lungs. The collapse sometimes involves the whole of one lobe, but more commonly it is limited to much smaller areas of the lung. When scattered and limited in its distribution there is usually more or less emphysema of the intervening portions of the lung; when collapse is very extensive in the lower lobes emphysema is most marked in the upper.

Those portions of the lung in which the pneumonic process has supervened appear most commonly as scattered patches and nodules of consolidation, varying in size from a small pea to a hazel-nut. These are usually more or less conical in shape, with their bases towards the pleura, which membrane is generally unaffected over them, though it may be coated with lymph. On section the patches are commonly ill-defined and pass insensibly into the surrounding tissue, which is variously altered by congestion, collapse, and emphysema. They are of a reddish-grey colour, slightly elevated, smooth, or faintly granular, and soft and friable in consistence. As they increase in size, they may become confluent, and thus are produced large tracts of consolidation. In a more advanced stage, the nodular and more diffuse consolidation becomes paler, firmer, and drier, and resembles in colour the greyish-yellow hepatisation of acute pneumonia. The cut ends of dilated bronchi, filled with pus, are occasionally seen in the centres of the pneumonic nodules. The pneumonic process often involves the collapsed portions of lung, which then become more opaque and swollen. In septic broncho-pneumonia the pneumonic patches often suppurate, and sometimes contain sloughs of lung-tissue.

Microscopical characters. — When examined microscopically, the pneumonic patches are seen to consist of an accumulation within the alveoli of a gelatinous mucoid-looking substance, leucocytes, epithelial elements, and red blood-corpuscles. The epithelial elements are swollen and granular. In some cases much of this accumulation is precisely similar to that contained in the smaller bronchi, and it is evidently the inflammatory and richly cellular bronchial secretion which has been inhaled. The relative proportion of epithelium and leucocytes varies considerably in different cases, the latter being more numerous in acute, and especially in septic cases.

The subsequent changes which take place in the lungs vary. When the disease does not end in death, resolution is the most common termination. The contents of the alveoli undergo fatty degeneration, and are removed by expectoration and absorption, the lung gradually regaining its normal characters. This process, however, is less readily effected than in the consolidation of acute pneumonia; and it sometimes occupies such a lengthened period, that some thickening of the bronchial and alveolar walls and dilatation of the smaller bronchi remain. In still more chronic cases the fibroid thickening is much more marked, and a considerable amount of irregularly distributed, pigmented induration and bronchial dilatation may be produced. Caseation occurs only in tubercular cases.

SYMPTOMS.—The symptoms of broncho-pneumonia vary according to the rapidity with which the disease is developed, the extent of lung in-

volved, and the nature of the disease in the course of which it supervenes.

The more severe and most common forms of the disease are met with in early childhood in association with simple bronchitis, and the specific bronchitis of measles and whooping-cough. In these cases the symptoms and dangers are, in the main, those of the capillary bronchitis which precedes the pneumonic process, and it is sometimes impossible to distinguish between them. Frequent cough, accelerated respiration, slight action of the nares, and other symptoms of severe bronchitis, with a little pyrexia, precede for a varying length of time the symptoms due to the implication of the lung-tissue. The earliest symptoms of the pneumonic process are by no means well-defined, and consequently the time at which the lung becomes involved cannot be fixed with certainty. Rigors, convulsion, and vomiting are but rarely observed. Usually an increase in the acceleration of the respiration or in the dyspnoea, and a marked rise of temperature, are the first signs of the pulmonary implication. The breathing becomes more rapid, and commonly causes much distress, the child tossing about and being exceedingly restless. The dyspnoea is more marked at some times than at others, and is occasionally more or less distinctly paroxysmal. The respiration is superficial, inspiration being short, and the expansion of the thorax imperfect. There is marked action of the accessory respiratory muscles, and the upper portions of the thorax are raised, while the lower and the soft parts are retracted during the inspiratory act. The action of the nares is very pronounced.

An increase in any pyrexia which attended the pre-existing bronchitis is, with few exceptions, observed as the lungs become involved, and such increase is to be regarded as one of the most valuable indications of the existence of a pneumonic process. The maximum temperature of acute simple bronchitis, even in the child, is seldom higher than 102° F., whereas that of the secondary pneumonic process is often 104° or 105°. This increase usually occurs more or less gradually; there is rarely the sudden rise of temperature met with in acute pneumonia. Unlike the temperature of this disease also, the fever of broncho-pneumonia runs no definite course. It varies with the extent of the lung-implication, and with the rapidity with which this implication is effected. There is no regular diurnal variation; the remissions and exacerbations are often considerable; and they occur at irregular times, the temperature being sometimes higher in the morning than at night. The cough, which before the implication of the lung was paroxysmal in character, gradually becomes less and less so, and it now often causes much pain to the patient. The sputa, when present, are bronchitic in character, usually tenacious, and occasionally streaked with blood; as, however, expectoration rarely occurs in the child, they are not often seen. The pulse is much increased in frequency, in children under five years often being 150. It may in the earliest stage of the disease be moderately full and strong, but it quickly becomes soft, small and feeble. In addition to the above, there are often symptoms referable to the digestive organs. Of these diarrhoea is the most important. This is quite frequent, especially when the disease follows measles. It is very readily induced by medicines

and by improper feeding ; and as it greatly weakens the patient, it is important that this liability to diarrhoea should be kept in mind. Vomiting, as already stated, is very rare as an initial symptom ; it is, however, common in the course of the disease, especially as a result of cough, the bronchial secretion, together with the contents of the stomach, often being expelled.

As the bronchitis and the implication of the lungs increase, the breathing becomes still more rapid and superficial ; the dyspnoea is more marked ; the expression is anxious ; the face is pale ; and symptoms of carbonic-acid poisoning become evident. Strength now fails ; the face and lips become cyanotic ; and the extreme restlessness gives place to apathy and a semi-comatose condition, which is interrupted from time to time by ineffectual efforts to cough. With the rapid failure of strength and increasing cyanosis, cough almost ceases ; the pulse becomes exceedingly feeble ; and the child, often extremely emaciated, may die exhausted, and in a condition of more or less profound coma. Sometimes death occurs suddenly during a paroxysm of cough, or with convulsions.

In those cases in which capillary bronchitis constitutes a less prominent feature of the illness, the symptoms are usually less severe—the pyrexia is less marked and its onset more gradual ; the pneumonic process often supervenes later ; and the course of the disease is more protracted. A slight and markedly irregular pyrexia, increasing difficulty of breathing, with loss of strength and flesh, may continue for months, and the child ultimately die, or recover with more or less damaged lungs. In these more chronic forms of the disease, which are perhaps most common after whooping-cough, the pneumonic process is often less disseminated, and involves larger areas of the lung—sometimes a whole lobe.

When broncho-pneumonia occurs in adults and in the aged, the symptoms are for the most part much less pronounced than in the child. In strong adults the disease is perhaps most common after diphtheria, and here the pulmonary symptoms may be well-marked ; but in the debilitated, and especially in the old, the course of the disease is more latent, some pyrexia, slight cough and dyspnoea, and marked debility being the principal symptoms observable.

In the aged and feeble, broncho-pneumonia is frequently associated with that form of lung-consolidation which results from weak inspiratory power, feeble circulation, and gravitation ; and which consists mainly of collapse, hyperæmia, and cedema of the lung-tissue (hypostatic pneumonia). This hypostatic consolidation may exist quite independently of bronchial catarrh ; but when such catarrh occurs in the aged and feeble, gravitation often determines the supervention of the pneumonic process, which under such circumstances is consequently not infrequently unilateral.

When the more acute varieties of broncho-pneumonia terminate fatally, they usually do so from the tenth to the fourteenth day of the disease ; and in infants death may occur much earlier. Death, unlike that from acute pneumonia, is mainly due to the interference with the respiratory function, and, to less extent, to cardiac failure. The interference with the respiration is usually much greater than in acute pneumonia, for, in addition to the diminution of the respiratory area, due to the pul-

monary consolidation and collapse, there is the much more important cause of interference—namely, the impediment to the entrance of air, caused by the swelling of the bronchial mucous membrane, and the accumulation of secretion in the smaller bronchi. Over-distension and failure of the right heart occur here as in ordinary pneumonia. In the more chronic forms of broncho-pneumonia death may not occur for some months, and then it results as much from general failure of strength as from interference with the respiratory function.

When the disease does not terminate in death, improvement in the symptoms is usually gradual. The temperature falls slowly, several days, and occasionally some weeks, being occupied in the completion of defervescence ; and this gradual decline is often interrupted by more or less marked and frequent exacerbations and remissions of the fever. The cough and dyspnoea diminish, and the appetite gradually returns ; but restoration to health is often protracted ; and the child remains for some time liable to repetition of the bronchial symptoms. In some cases, however, the disease clears up much more rapidly, and in three or four days all signs of consolidation may disappear.

Sometimes recovery is not complete, and the disease leads to some induration of the lung, and dilatation of the bronchi. Emphysema and pulmonary tuberculosis are occasional sequelæ.

Physical signs.—The physical signs of broncho-pneumonia are in the main those of capillary bronchitis. Imperfect expansion of the thorax, elevation of the upper portions, and recession of the lower, during the inspiratory act ; rhonchi and moist râles, audible over both sides ; and the absence of any marked alterations in percussion-resonance, are the principal signs observable, not only in the earlier stages, but throughout the whole course of the disease. The recession of the chest-walls is increased by the collapse. The pulmonary implication is indicated rather by the symptoms—increase in the pyrexia and in the dyspnoea—than by any marked alteration in the physical signs. The difficulty of detecting the lung-consolidation is due to its usually being limited, in the earlier stages, at all events, to small areas, which are surrounded by healthy or emphysematous lung, so that resonance on percussion is but little impaired. It is only when these small areas have coalesced into larger areas of consolidation, that any marked alterations in percussion-resonance are discoverable. The impaired resonance due to collapse is not to be distinguished from that due to pneumonic consolidation ; and, inasmuch as the collapse is so often symmetrical, involving both bases posteriorly, the difficulty of appreciating it is increased. Much more valuable aid in physical diagnosis is in most cases to be obtained from auscultation. Over those portions of the lung where consolidation has taken place, the moist bronchitic râles tend to assume a somewhat metallic quality ; they also become finer, though not so fine as true pneumonic crepitation ; and they are more superficial. The detection of these superficial, somewhat metallic fine moist râles, heard with inspiration, and not dispelled by cough, over small areas of the lungs, especially at the posterior bases, is a most valuable and often the only physical sign of the pulmonary implication. If larger areas become consolidated, there may be in addition some tubular breathing, and some impairment of resonance on percussion ; and when a

whole lobe is involved the physical signs become increasingly pronounced, and in a young child a bronchophonic cry is often marked on auscultation.

COMPLICATIONS.—Pleurisy is less common than in acute pneumonia. Slight inflammation of the pleura is, however, usually found *post mortem* over those portions of the lung which are consolidated. Pleuritic effusion is rare. Intestinal catarrh is an important and common complication. The liability to this in the child, and the mechanical congestion resulting from the obstructed pulmonary circulation, must be borne in mind in explaining its frequency.

DIAGNOSIS.—The diagnosis of broncho-pneumonia is occasionally difficult. This difficulty is mainly owing to the co-existence of capillary bronchitis. The recognition of the pulmonary implication in its earlier stages is often impossible. The increased pyrexia and frequency of respiration are the symptoms of the most diagnostic value. Owing to the small areas of lung involved, any alteration in the physical signs of the capillary bronchitis may be entirely wanting. The occurrence of extensive collapse in the earlier stages gives more marked physical signs of consolidation, and hence renders the diagnosis more easy. It is almost impossible to diagnose certainly, either by symptoms or by physical signs, between the collapse and the pneumonic consolidation. This, however, is of but little practical importance, inasmuch as the collapse is usually associated with, and often the immediate precursor of, the pneumonic process.

The diagnosis of broncho-pneumonia from acute pneumonia may occasionally be difficult in those cases of the former disease in which an extensive area of the lung has become consolidated. The history of the case, and especially the course of the pyrexia, will usually suffice to distinguish them.

The greatest difficulty is in connection with tuberculosis—to distinguish between a simple and a tubercular broncho-pneumonia is often possible only after prolonged observation. In the more protracted cases so common in children after the age of infancy, the possibility of tuberculosis must always be borne in mind. A persistence of the physical signs and of some irregular pyrexia is always suspicious. Examination of the upper lobes for any sign of softening; and of the sputum for tubercle-bacilli and elastic tissue may help the diagnosis. In young children who do not expectorate sputum may sometimes be obtained by the exhibition of an emetic.

PROGNOSIS.—The two circumstances which have an especial influence upon prognosis in broncho-pneumonia are the age of the patient, and the general health. Before puberty, the younger the patient the graver the prognosis. In children under five years, the mortality is probably about 20 per cent. The disease is especially fatal in weakly children, in those debilitated by previous illness, and when occurring in measles and diphtheria. The existence of rickets materially increases the gravity of prognosis. The danger also increases greatly with the extent of lung involved, much more so than is the case in acute pneumonia. Of the value of the several symptoms as influencing prognosis, after the description which has been given of the disease and of the modes in which it tends to cause death, it is hardly necessary to speak further. Symptoms of imperfect aëration of blood, lividity, emphysema, cessation of cough, together with a distended and failing right heart, are those most to be feared.

In protracted cases the possibility of tuberculosis must be remembered.

TREATMENT.—In the treatment of broncho-pneumonia, it is important to bear in mind—first, that the disease is generally associated with capillary bronchitis, and with more or less pulmonary collapse; second, that its occurrence is especially favoured by everything that weakens the patient; and, third, that it tends to destroy life principally by interfering with the function of respiration, which interference necessarily increases with the consequent weakening of the respiratory power. Such being the facts, it is obvious that the main object of treatment will be, first, to control the bronchitis, and endeavour so to modify it as to prevent the occurrence of collapse; and, secondly, to support as much as possible the strength of the patient.

It would be out of place in the present article to enter into a detailed description of the management of acute bronchitis (*see* BRONCHI, Diseases of). It will be sufficient to indicate the more important means of controlling the disease.

The patient should be kept in a warm room, about 65° F., the temperature never being allowed to fall below 62°. The room should be well but carefully ventilated; and protection from draughts is important—much more so than in the treatment of acute pneumonia. It is also advisable to keep the air moist by means of a steam-kettle, as the exhalation of water from the lungs is thus diminished, and the bronchial secretion consequently rendered less tenacious, and more easily removed by cough. A little carbolic acid (1 in 60) or tincture of benzoin may be added to the water. A tent to enclose the steam is sometimes advisable, but as this tends to interfere with the supply of oxygen and to weaken the patient, it must be used with caution. The diet, which must be regulated according to the age of the patient, should be nutritious and easily digestible, the importance of supporting the strength being kept in mind. When the disease follows measles, the liability to gastro-intestinal catarrh must not be forgotten. The chest should be covered with a cotton-wool jacket, and either a lightly made linseed-and-mustard poultice, or some stimulating liniment sprinkled on flannel, be applied alternately front and back.

Medicinally, small doses of ipecacuanha with salines, and carbonate of ammonium, should be administered frequently. Evidence of accumulation of the secretion from weakness or ineffectual cough calls for increased doses of the ammonia; and under these circumstances small doses of Apomorphine Hydrochlor. may often be added with advantage—for a child gr. $\frac{3}{30}$ to gr. $\frac{1}{30}$. An occasional emetic often materially relieves the patient: for a child, Vin. Ipecac. $\frac{3}{4}$, for an adult Ammon. Carb. gr. xxx. given in hot water every fifteen minutes until vomiting occurs. When cough is paroxysmal and causes much distress, belladonna in full doses is often of great benefit. The exhibition of opiates obviously requires great caution, and in children they are contra-indicated.

Signs of heart-failure call for the exhibition of brandy, and children bear stimulation well. An infant may begin with from five to ten drops every two or three hours. If with failure the right heart is distended, the jugular veins full, and much dyspnoea, the question of leeching or venesection should be considered. Leeches over the sternum are often useful: in the child three or four may be

applied. Strychnine is also most valuable, stimulating both the heart and the respiratory centre. It is best given hypodermically (Liq. Strych. Hydrochlor. m.j.) for a child every three or four hours. Oxygen is less useful than in acute pneumonia.

The external application of cold is sometimes useful in the acute forms of the disease so common in early life. This not only reduces the temperature, but appears to be especially valuable in increasing the depth and force of respiration, and thus in preventing the occurrence of collapse. Its utility has been strongly advocated by both Bartels and Ziemssen, who recommend the frequently renewed application of cold wet compresses to the chest. The use of tepid baths, with cold affusions, is a more efficient way of obtaining the same result. The child is placed in a bath of from 85° to 90° F., and, while immersed, the head, back, and chest are quickly sponged with cold water. This repeated occasionally, with due precautions, is often followed by reduction of temperature, a diminution in the frequency and an increase in the depth of the respirations, and other signs of improvement. The application of ice-bags or ice-poultices to the chest sometimes yields good results. The effects produced by the cold require in all cases to be carefully watched, and any depression caused should be met by the timely exhibition of stimulants.

In the more chronic forms of broncho-pneumonia these active methods of treatment are but rarely called for. Here attention to strength and nutrition is most important, and small doses of cod-liver oil in the later stages, even before the complete disappearance of the pyrexia, are often useful. When the disease leads to induration of the lungs and dilatation of the bronchi, the treatment resolves itself into that of chronic pneumonia.

Convalescence, it must be remembered, is usually slow, and there is a tendency to relapse. Great care is consequently requisite during this period. All causes of catarrh must be carefully guarded against; and the restoration to health assisted by nutritious diet, cod-liver oil, and preparations of iron. A change of air is especially valuable.

C. Chronic Pneumonia.—**SYN.**: Interstitial Pneumonia; Cirrhosis of the Lung; Fr. *Pneumonie Interstitielle*; Ger. *Lungencirrhose*.

DEFINITION.—Chronic pneumonia is a comparatively rare disease, characterised by a gradual increase in the connective tissue of the lung, which leads to an induration of the pulmonary texture, and to progressive obliteration of the alveolar cavities. It is commonly associated with catarrh and dilatation of the bronchi, and often with ulceration of the bronchial walls, and excavation of the indurated lung. Cough, expectoration—often abundant, but varying with the bronchial catarrh—dyspnoea, gradual impairment of nutrition, and occasional accessions of slight pyrexia, are the most prominent clinical phenomena accompanying the disease, which runs an exceedingly chronic course, often subject to long periods of quiescence, but tending to terminate fatally in from five to fifteen years.

ETIOLOGY AND PATHOLOGY.—In the large majority of cases chronic pneumonia is the result of some antecedent inflammation of the bronchi, alveoli, or pleura, although cases are sometimes met with in which no history of any such antecedent affection is discoverable. It may be stated generally that all inflammatory processes in the lungs, as in other organs, which become chronic, lead to

an increase of the connective-tissue elements, and consequently to fibroid induration of the organ. In the lungs by far the most common cause of such induration is chronic pulmonary tuberculosis. In all cases of phthisis, excepting those which are the most acute, there is more or less fibroid growth; and the extent of this growth is, for the most part, in direct proportion to the chronicity of the disease. Those forms of tuberculosis which are the most chronic, and in which the fibrosis reaches its maximum, have been termed 'fibroid phthisis.' Such cases, it must be admitted, are somewhat closely allied to some forms of chronic pneumonia. The two diseases, however, differ pathologically in this respect—that, whereas much of the pulmonary consolidation of tuberculosis tends to undergo molecular death and caseation, that of chronic pneumonia exhibits no such tendency; but any destruction and excavation of the indurated lung which may take place is due to secondary inflammation and ulceration commencing in the bronchial walls. In considering the pathology of chronic pneumonia, therefore, it is necessary to exclude the fibrosis due to chronic pulmonary tuberculosis.

The chief causes of chronic pneumonia are:

(1) *Acute pneumonia.*—The pulmonary consolidation of acute pneumonia almost invariably undergoes complete resolution. This resolution is usually effected rapidly, in from seven to fourteen days. In very exceptional cases, however, the process is so protracted as to lead to some thickening of the walls of the alveoli, and sometimes to organisation of their contents. This indurated hepatisation differs but little in its physical characters from ordinary red and grey hepatisation; it is simply somewhat firmer, more resistant, and less granular. It is probable that this small amount of induration commencing in the alveolar walls may gradually increase, so as ultimately to give rise to that extensive fibrosis of the lung which constitutes what is usually known as chronic pneumonia.

(2) *Broncho-pneumonia.*—Broncho-pneumonia is a more frequent cause of the disease than the preceding (Wilson Fox). The greater liability of this form of pneumonia to lead to pulmonary induration is to be accounted for partly by its longer duration and greater tendency to become chronic, and partly by the existence of bronchial dilatation with which it is so often associated. The accompanying collapse, so frequent in children, is also an important factor in the causation of the fibrosis. That bronchial dilatation is favourable to an indurative pneumonic process has been especially insisted upon by the late Wilson Fox. Dilatation of the bronchi is exceedingly common in the simple and specific bronchitis of childhood, and especially in that associated with whooping-cough; it is also a direct result of pulmonary fibrosis. In whatever way originating, its existence favours the persistence of the catarrhal and pneumonic processes. The removal of secretion is rendered more difficult; the retained secretion tends to increase and keep up the irritative process, both in the dilated bronchi and also in the pulmonary alveoli; and this persistence of the bronchial and pulmonary inflammation leads to fibroid thickening of the bronchial and alveolar walls. In this way more or less disseminated patches of indurative consolidation are produced, which, as the process goes on, gradually increase, so that ultimately they may involve large areas of the lung. The progressive tendency of the

process may be partly due to the fact, already stated, that pulmonary fibrosis is a cause of bronchial dilatation, so that fibrosis once established, by inducing further dilatation of the bronchi, favours the extension of the bronchial and pulmonary induration.

(3) *Pleurisy*.—Pleurisy in exceptional cases leads to the development of a chronic pneumonia. It appears to be in those cases of pleurisy which are more or less chronic, and in which the lung remains long collapsed from the effusion, that such a result is most liable to occur. The induration of the lung thus induced is sometimes, however, exceedingly partial, consisting merely in some increase of the interlobular connective tissue originating and extending inwards as dense bands from the thickened visceral pleura. In other cases pleurisy gives rise to a much more general fibrosis.

(4) *Inhalation of solid irritating particles*.—This, which occurs in miners, potters, stonemasons, grinders, &c., is the cause of the fibrosis of the lungs so common among persons so employed. The continuous irritation of the inhaled particles induces a bronchial and alveolar inflammation, and ultimately a progressive fibrosis, which, gradually extending, may involve large areas or even the whole of the lungs. These cases often become tuberculous. *See PNEUMOCONIOSES*.

(5) *Atelectasis*.—Collapse of the lung which has existed for some time may lead to more or less fibrosis of the affected area.

(6) *Syphilis*.—A diffuse interstitial pneumonia is an occasional result of congenital syphilis.

ANATOMICAL CHARACTERS.—The histological changes met with in the lungs in chronic pneumonia may be described generally as consisting in the development of a fibrous tissue from the walls of the alveoli, from those of the bronchi, and from the interlobular connective tissue; which new growth, as it increases, and from its tendency to contract, gradually replaces and obliterates the alveolar structure. The character of these changes, however, varies somewhat according to the inflammatory antecedents in which they originate. When the result of acute pneumonia, the primary, and usually the principal, change takes place in the walls of the alveoli, although ultimately the interlobular tissue is involved. The alveolar walls become thickened by the growth of a small-celled tissue, which, in its earlier stages, usually contains new blood-vessels. The alveolar cavities which are not obliterated are either empty, or contain exudation-products and a few epithelial cells. In some cases the intra-alveolar exudation becomes organised.

When secondary to ordinary broncho-pneumonia, or to that induced by the inhalation of solid irritating particles, the new fibroid growth also originates principally from the alveolar walls. Here, however, in the earlier stages it is less uniform, and the peri-bronchial and interlobular connective tissues play a more prominent part in the process. The new peri-bronchial tissue invades the walls of the adjacent alveoli, and materially increases the fibrosis.

In the chronic pneumonia resulting from pleurisy, the change, as already stated, is usually more localised, consisting in the development of dense fibrous bands passing inwards from the thickened pleura. These are developed from the interlobular tissue. In other cases the fibrosis is more general.

In whichever of the pulmonary structures the new fibroid growth originates, all the connective tissue

of the lung may ultimately become involved, and as it increases the alveolar cavities may be completely obliterated.

The macroscopical appearances of the lung vary with the extent of the fibroid change. In the earliest stages of the induration resulting from acute pneumonia, where there is merely a slight thickening of the walls of the alveoli, the consolidation very much resembles that of red or grey hepatitis. It differs in being firmer and less friable in consistence, and is somewhat less granular. In the later stages, and in all cases where the fibrosis is extensive and general, the appearances presented by the lung are very characteristic. The organ is diminished in size, dense, firm, fibrous, in parts almost cartilaginous in consistence. The cut surface is smooth; and the large amount of irregularly distributed black pigment usually present gives to it a peculiar grey, marbled appearance. Numerous dilated bronchi traverse it in all directions.

The bronchi are almost invariably found dilated in those portions of the lung where the induration is advanced. This dilatation is often very considerable, the dilated tubes forming cavities, which may occupy a large portion of the indurated lung. The walls of the tubes are much thickened, and the mucous membrane is often ulcerated. This secondary inflammation and ulceration of the bronchi, which occurs especially in the dilated portions, is induced by the irritating and often putrid secretion which they contain. It may extend into and involve the indurated lung, and so lead to more or less excavation. The mucous membrane sometimes sloughs, and the gangrenous process may involve the lung. The cavities so common in these lungs are in the main, however, dilated bronchi. *See BRONCHI, Diseases of*.

The pleura of the affected lung, except in the earliest stages of the disease, is much thickened and adherent.

Site.—Chronic pneumonia is in the majority of cases unilateral. The whole lung may be involved or only a portion. In the latter case the base is much more commonly affected than the apex. When it is due to the inhalation of irritating solid particles, both lungs are usually implicated.

SYMPTOMS.—In the earlier stages of chronic pneumonia the symptoms are often very obscure, and it is not uncommon to meet with advanced and extensive fibrosis in which the lung-affection must presumably have been of much longer duration than the symptoms accompanying it. In some few cases the symptoms are directly continuous with those of some more acute pulmonary inflammation—an acute or a broncho-pneumonia. Under these circumstances, a prolongation of some of the phenomena of the original disease may indicate the superposition of the pulmonary fibrosis. The pyrexia does not entirely disappear. The cough persists, as does also some increase in the frequency of the respiration and pulse; and the patient, instead of improving, gradually loses strength and flesh. At the same time the physical signs of the pulmonary consolidation remain, and may gradually give place to those of pulmonary induration. Where chronic pneumonia is secondary to pleurisy, a continuous sequence in the symptoms is even less commonly observed. When it is the result of the inhalation of irritating solid particles, the symptoms of bronchial catarrh are predominant. *See PNEUMOCONIOSES*.

When the fibrosis is fully established the symptoms are usually more pronounced. They vary considerably, however, with the extent of lung involved, the situation of the consolidation, and especially according to the presence or absence of bronchial catarrh. When bronchial catarrh is absent, and the disease is quiescent, a considerable area, or even the whole of the lung, may be involved without producing any marked pulmonary symptoms; and slight dyspnoea and cough, with some general impairment of nutrition and failure of strength, may be almost the only phenomena present. Such quiescence and immunity from symptoms, however, although common in the course of the disease, are rarely observed over lengthened periods.

With the existence of catarrh of the bronchi, much more marked pulmonary symptoms are usually observable. Inflammation of the bronchi is especially favoured by their dilatation, and it is almost invariably present, to a greater or less extent, during the course of the disease. With it is usually associated activity of the indurating process. This dilatation of the bronchi, and secondary inflammation and ulceration of their walls, are most important factors in accounting for the symptoms. The course of the disease now often simulates that of chronic fibroid tuberculosis, but it is for the most part more chronic, less regularly progressive, and more frequently interrupted by periods of quiescence. The dyspnoea is now more marked, and cough becomes a troublesome symptom. The cough may be more or less constant, and it is usually attended by expectoration. Its characters vary, however, according to the situation and the extent of bronchiectasis. When, as is most frequent, the lower lobe of the lung is involved, the secretion accumulates, and its removal by expectoration is exceedingly difficult. Under these circumstances the cough is often violent and paroxysmal (*see BRONCHI, Diseases of*). The sputum may be simply mucopurulent, but when there is much bronchiectasis, owing to its accumulation and retention in the tubes, it often becomes septic, is of a greyish or greenish-black colour, and more or less fetid. This putrid secretion not only intensifies the inflammation in the bronchiectatic cavities where it originates, but is often conveyed by aspiration to other parts of the same, or the opposite lung, and so originates foci of broncho-pneumonia, which materially hasten the progress of the disease. Hæmoptysis is not infrequent, but it is usually small in quantity, and is in most cases due to ulceration of the bronchial walls.

Pyrexia is usually present to a greater or less extent in the course of chronic pneumonia. The fever, however, is exceedingly irregular, and there are often long periods of perfect immunity. During the pyrexial periods the maximum evening temperature is rarely more than 101° or 102° F., and it may be only 100° . The morning temperature is often normal. The pyrexia appears in most cases to be due to inflammation and ulceration of the bronchi. It is not infrequently the result of a supervening tuberculosis.

With the progress of the disease the patient gradually emaciates; the fingers become clubbed; digestion is impaired, and diarrhoea is often present. Dropsy is a common symptom, although it is rarely extensive, and is, for the most part, confined to the lower extremities. It appears in most cases to be due to the anæmia and impeded pulmonary circula-

tion. The pulmonary obstruction may also give rise to some enlargement of the right side of the heart, and cyanosis. Amyloid disease of the viscera is occasionally met with. Death usually results from the general failure of strength, or from some intercurrent affection of the opposite lung.

Physical signs.—In the earliest stage of chronic pneumonia, when it is the result of a more acute pneumonic process, the physical signs are, in the main, those met with during the acute consolidation. It is the persistence of the signs of the pulmonary consolidation that indicates a supervening fibrosis. Dulness on percussion; increased vocal fremitus; bronchial breathing; and the existence of *râles*, which are larger, moister, and more metallic in quality than those of fine crepitation, are observable during this stage. When the induration is fully established, the physical signs are those of contraction and consolidation of a whole or a portion of the lung, with usually those of more or less bronchiectasis. The retraction is well marked, and commonly affects the whole side, although when the lung is not universally involved it may be more limited. Expansion is deficient, or completely absent. The heart is displaced towards the affected side; the diaphragm and the abdominal viscera are drawn up; and the opposite lung may encroach considerably across the middle line in front. Percussion is hard, wooden, and high-pitched, sometimes more or less amphoric. If there be much pleural thickening, vocal fremitus may be diminished or absent, but vocal resonance is always increased. The respiratory sounds will vary according to the extent of the bronchial dilatation and excavation, and the amount of secretion. They are for the most part bronchial; usually large and loud; and often distinctly cavernous. When there is much secretion in the dilated bronchi, high-pitched bubbling *râles* are heard, which are often amphoric and cavernous. These may be audible only after cough. The opposite lung is usually enlarged and hyper-resonant, and the respiratory movement exaggerated.

DIAGNOSIS.—The diagnosis of chronic pneumonia rests mainly on the physical signs. The disease with which it is most liable to be confounded is chronic fibroid tuberculosis. The physical condition of the lungs and the symptoms of the two diseases are sometimes deceptively similar. In those quite exceptional cases in which chronic pneumonia involves only the upper lobe, the situation of the consolidation is very greatly in favour of its tubercular nature. This probability is infinitely increased if the other lung be affected. In unilateral basic disease, and in induration of the whole of one lung, the other lung being healthy, the tubercular nature of the disease is much less probable; although the occasional supervention of a tuberculosis in these cases, and also the possibility of a primary basic tuberculosis, must be borne in mind. Repeated examinations of the sputum for the *Bacillus tuberculosis* is usually the only means of settling the diagnosis.

PROGNOSIS.—Chronic pneumonia, when it involves a considerable area of the lung, usually tends ultimately to terminate in death, although under favourable circumstances life may be prolonged for many years. When the disease is limited, and remains quiescent, the general health and duration of life may sometimes be but little affected. The most important element in the prognosis is the con-

dition of the bronchi. The existence of bronchial dilatation, as evidenced by profuse, and often foetid, expectoration, is always unfavourable, as it not only weakens the patient, but is usually attended by extension of the induration, and may ultimately lead, in the dilated tubes, to ulceration of the bronchial walls and surrounding tissue, and occasionally to gangrene. Pyrexia, as another evidence of inflammation of the bronchi and indurated lung, is likewise unfavourable, as is also hæmoptysis. The latter indicates deep ulceration, and it may in exceptional cases endanger life. The general condition of the patient must also be taken into account in making a prognosis. Failure of strength and of digestive power, diarrhoea, and dropsy, are all of unfavourable augury.

TREATMENT.—In considering the treatment of chronic pneumonia, it is in the first place important to bear in mind that the usual origin of the disease is some more acute pulmonary inflammation. Hence the necessity for the most careful management and supervision of such inflammations in their later stages, with the object of procuring, if possible, a complete resolution of the pneumonic products.

When the fibrosis of the lung is established, it is hardly necessary to remark that the new growth is incapable of removal, and by treatment we can only hope to influence the extension of the disease, and control the bronchial catarrh with which it is so frequently associated. The frequency and gravity of bronchial catarrh has been already insisted upon; and its management, in the majority of cases, constitutes by far the most important element in the treatment. Our object must be to prevent and control it; to promote expectoration, and to prevent that decomposition of the secretion which is so apt to result from its retention. Here the question of climate will necessarily present itself, and very much may usually be done by residence at some suitable station. One not subject to vicissitudes of temperature, and at the same time dry and moderately bracing, is most likely to be beneficial. The patient should be warmly clad, and everything should be done, by means of diet and medicine, to improve the general health. Cod-liver oil and iron are often useful for this purpose. If an attack of acute bronchial catarrh supervenes, it should be treated at once, and the importance of quickly controlling it should not be forgotten.

In the treatment of the more chronic catarrhal process which is so often associated with profuse secretion, much may usually be gained by the use of stimulating and antiseptic inhalations, of which creosote, eucalyptus, and carbolic acid are, perhaps, the most generally useful. These not only tend to diminish the amount of secretion, and to prevent sepsis, but induce coughing, and so assist in its evacuation. These substances may be administered internally with the same object. Counter-irritation, especially painting with iodine, appears sometimes to be serviceable. Gastric disturbance, diarrhoea, hæmoptysis, &c., must be treated, as they arise, on general principles.

In cases of localised basic disease, when other treatment fails, the question of paracentesis and artificial drainage of a large bronchiectatic cavity might be entertained.

T. HENRY GREEN.

(Bacteriology) JOHN EYRE.

LUNGS, Inflation of.—This term is applied to two conditions. It sometimes signifies that condition in which the lungs are acutely and temporarily distended more or less with air, as in some cases of bronchitis, a condition which is usually called 'acute emphysema.' It does not give rise to any definite symptoms; but it can be made out by physical examination, the signs being those indicating distension of the lungs. No treatment, other than that of its cause, is needed.

'Inflation' is also a term applied to intentional expansion of the lungs with air, as carried out in certain methods of artificial respiration.

FREDERICK T. ROBERTS.

LUNGS, Malformations of.—There are no malformations of the lungs which can be regarded as of much importance from a clinical point of view. As anatomical peculiarities, the shape of these organs, or the arrangement of their lobes, may be abnormal.

LUNGS, Malpositions of.—These are rare. The most important malposition of the lung is that known as *hernia*, in which a portion of the organ projects into the neck, or through some part of the chest-walls, or through the diaphragm into the abdominal cavity. If the hernia passes towards the surface of the body it may be made out clinically, being indicated by a soft and compressible swelling under the skin, localised, resonant on percussion, and rendered more prominent by a cough. Pulmonary symptoms are usually entirely absent. It is practically impossible to detect a hernia of the lungs through the diaphragm.

FREDERICK T. ROBERTS.

LUNGS, Morbid Growths in.—Neoplastic growths in the lung are so frequently either secondary to similar growths in the mediastinum, or in the case of primary growths, mainly diagnosed on account of the invasion of parts outside the lung itself, that it is convenient to consider all forms of new-growth occurring within the thorax under **MEDIASTINUM, Diseases of.**

LUNGS, Œdema of.—**SYNON.:** Fr. *Œdème du Poutmon*; Ger. *Lungenödem*.

DEFINITION.—Infiltration of the pulmonary tissue with serous fluid.

The serous fluid is effused from the pulmonary capillaries into the pulmonary connective tissue, and into the alveolar and bronchial spaces.

ÆTIOLOGY.—The causes of this exudation are manifold, but of two sorts:—(a) *Disordered circulation:* (1) active congestion, attendant upon inflammatory conditions of the lungs and bronchi; (2) hypostatic congestion; (3) mechanical congestion—in heart-disease, emphysema, or pressure upon the pulmonary veins; (4) want of tone of vessels after inflammatory conditions, as pneumonia or bronchitis, or pressure upon the vagus nerve or pulmonary plexus; (5) afflux of blood to the lungs in croup, and during the asthmatic paroxysms determined by the ineffectual efforts at inspiration. (b) *Morbid conditions of the blood:* in albuminuria, and to a less degree in other diseases in which the condition of the blood is altered or impaired—for example, scurvy, purpura, anæmia, hydræmia—the lungs partaking of the general disposition to dropsy.

ANATOMICAL CHARACTERS.—In cases of œdema pulmonum, the lungs are usually large, filling the

thoracic cavity, and sometimes indented by the ribs. They are heavy; their pleural surfaces are wet; and the pleural cavities contain an excess of serum. Both lungs are as a rule affected, their lower and most dependent portions chiefly; and one lung, on the side to which the patient has last inclined, is more highly oedematous than the other. The higher the degree of oedema the less crepitant the lung, and the more distinctly the surface pits on pressure. A portion cut from a simply oedematous lung will, however, almost always float in water; but at the base of the lung there is usually some collapse in addition to the oedema, and a portion removed therefrom sinks. On section the lung exudes abundant thin serum, and more or less frothy fluid, with which the bronchial tubes are also occupied. On first making a section the succulent tissue will break down easily under the finger; but after the excess of fluid has been squeezed out, the lung feels toughened. The fluid is almost entirely confined to the alveolar spaces and parenchyma proper, as distinguished from the interlobular septa of the lung. Oedema may be found at any portion of the lung—at the apex, for instance, determined there by the inflammatory process. The transition between oedema and inflammatory consolidation is very gradual. Oedema is also very apt to pass into, or to be complicated with, a certain degree of inflammation. The degree of friability, and of compressibility, and the application of the water-test, are the readiest methods of distinguishing between the two. If a portion of oedematous lung be examined under the microscope the alveoli are found to contain more or less numerous large granular cells, but these are never so numerous as to occupy entirely the alveoli.

SYMPTOMS.—The symptoms of oedema of the lungs are—in addition to those of the disease which has produced it—dyspnoea, which may amount to orthopnoea; troublesome ‘retching’ cough; and difficult, yet tolerably abundant, frothy, serous expectoration. The percussion-note is deadened at both bases, although the dullness is usually more extensive at one base than the other; the vocal fremitus is diminished; the respiratory murmur is enfeebled or lost; and a fine bubbling crepitation is heard.

DIAGNOSIS.—The diagnosis of pulmonary oedema is not usually difficult. The absence of pleuritic pains and of fever, and the double-sidedness of the disease, together with the absence of any true bronchial breathing or ægophony, will exclude pneumonia or pleurisy. The presence of dullness will also distinguish the condition from simple capillary bronchitis, with a certain degree of which, however, it is often combined. The general condition of the patient, and the presence or absence of those diseases or circumstances which are known to produce oedema of the lungs, must be carefully taken into consideration. If, for instance, after an asthmatic paroxysm we hear some fine bubbling *râles* over the bases of the lungs, and find the patient expectorating an unusual quantity of frothy serous fluid, we may suspect pulmonary oedema rather than bronchitis.

PROGNOSIS.—The prognosis in oedema of the lungs depends mainly upon the general or local conditions with which it is associated. It is of very grave purport in chronic Bright’s disease, or in heart-disease. It is also a grave complication in chronic bronchitis, showing failure of heart-power.

It is, however, often a transient and unimportant condition when it succeeds to acute chest-affections, as pneumonia or bronchitis, or to asthma. As a complication of acute chest-affections, it is rarely recognised clinically.

TREATMENT.—Kidney- or heart-disease, if present, will mainly determine the exact treatment. If there be failure of cardiac power, ether, ammonia, and alcoholic stimulants are required; and if the heart’s action continues hurried or irregular, digitalis is especially indicated. Hydragogue purgatives should be administered, according to the strength of the patient. Diuretics are useful in some cases, especially the vegetable diuretics, such as digitalis, juniper, and scopolarium, as also spirit of nitrous ether; and the same is to be said of diaphoretics—for example, acetate of ammonium, warmth, hot-air baths. Moderate stimulation and support must be kept up. When we suspect a loss of tone of vessels, as after bronchitis or pneumonia and in anæmic states, perchloride of iron with some mineral acid is to be recommended.

Locally, poultices are to be applied to the chest, with sufficient mustard to produce redness. Dry-cupping will often give great relief (p. 358). Blisters should be avoided. In all cases rest in bed or on a couch is necessary. R. DOUGLAS POWELL.

LUNG, Perforation of.—**SYNON.** : The term *pneumothorax* is almost equivalent.

DEFINITION.—The formation of an opening through the pulmonary pleura, communicating with the interior of the lung.

ÆTIOLOGY.—Perforation of the lung may arise in many ways. Its causes may be classified under the four following headings:

1. *Penetrating Wounds*; for example, gun-shot wound, punctured wound, or laceration by a broken rib.
2. *Rupture of the Lung*; as sometimes occurs during violent expiratory efforts, e.g. in whooping-cough, parturition, &c.
3. *Diseases affecting the Pleura or neighbouring structures*; such as empyema, hepatic abscess or hydatid, or suppuration of the bronchial glands.
4. *Diseases affecting the Lung itself*; for instance, tuberculosis, emphysema, gangrene, hydatids, or cancer.

Of all the causes of perforation of the lung, tuberculosis is infinitely the most common. It is the rule in phthisis for pleuritic adhesions to form *pari passu* with the pulmonary lesion, and these adhesions are usually very firm and difficult to break down. In neither respect, however, does this rule always hold good. In some rare cases in the earliest stage of the disease a small tubercular nodule situated immediately under the pleura softens, and the pleura gives way. Again, at any stage of the disease an outlying tubercular mass, situated below the point to which the pleural adhesions have extended, may soften and rupture into the pleural cavity.

In the more acute cases of phthisis there is often a singular indisposition to the formation of pleural adhesions. The pulmonary pleura becomes covered with a thin, smooth, translucent layer of lymph, shining through which can be seen at several points opaque yellow spots. These spots are found to correspond with underlying caseous masses, by which the pleura has been undermined and deprived of its vascular supply. Pneumothorax has its most frequent

origin in rupture of the pleura at one of these yellow points.

Finally, sinuses are sometimes found leading from old cavities within the lung to the pleural surface. Occasionally these sinuses, the pleura being adherent, penetrate through the thoracic wall and point externally. In other cases they may open into the opposite pleural cavity.

ANATOMICAL CHARACTERS.—In all cases of pneumothorax, the affected lung is collapsed. In cases of old standing the collapse may be so complete, and the lungs so covered by the products of exudation, that the organ can be found only with difficulty. The opening may have closed, and is often difficult to discern. It may consist of a small slit, communicating with a cavity by a slanting sinus, so as to form a complete valve; or it may be of considerable size, and communicate widely with a cavity or bronchus. All degrees of patency between these two extremes occur. The position of the opening is very variable; it is most commonly situated somewhere on the lateral or convex side of the lung. The rupture is almost always into the pleural cavity on the same side. It may, however, take place into the opposite pleural cavity, through the mediastinal fold of pleura. The pleura is inflamed, and covered with lymph; and its cavity contains air and a greater or less quantity of purulent fluid. The heart is displaced, unless in some rare cases it be held by a strong adhesion. Some years ago the writer tested the degree of air-pressure present in ten cases of pneumothorax by means of a water-pressure gauge. In two cases it was *nil*; in one case it was equal to 1·25 inch; in two cases 2 inches; in one case 3·75 inches; in two cases 4 inches; in one case 5·3 inches; and in a double case it equalled 3·5 inches in one pleura, and 2·7 in the other. The gas effused approximates in composition to that of expired air, containing from 8 to 16 per cent. of carbonic acid. Sometimes sulphuretted hydrogen also is found in fetid cases.

SYMPTOMS AND SIGNS.—The symptoms and signs of perforation of the pleura are those of pneumothorax, followed by hydro- or pyo-pneumothorax. At the moment of attack sudden acute pain is felt in the chest, at the seat of rupture, and is immediately followed by great dyspnoea and shock. In a well-marked case the expression of face is peculiarly agonised and terror-stricken; the extremities are cold; damp sweats break out; the pulse is quick and small; and the respirations are exceedingly rapid. The position of the patient is that of orthopnoea, with an inclination forwards, and to the sound side; it is, however, frequently changed in the endeavour to gain breath. The voice is feeble and whispering. The urgency of the shock and dyspnoea depends upon the amount of useful lung suddenly disabled. If the patient survive the attack, after two or three days fever of a hectic character, with sweats, supervenes. In some cases, however, the symptoms of pneumothorax come on very insidiously.

Physical Signs.—The physical signs are very characteristic. There is enlargement of the side affected, and effacement or bulging of the intercostal spaces. The heart is displaced towards the sound side. The percussion-note is hyper-resonant or tympanitic over the side affected, except where (at the apex) the lung may perhaps be still adherent; and on auscultation either no respiration at all is audible, or amphoric breathing of a peculiar charac-

ter may be heard at one or more points, sometimes accompanied with the characteristic metallic tinkle. A peculiar metallic echo is heard if the patient coughs. If, while the ear is applied, a coin placed on the diseased side is struck with another coin, a characteristic bell-note is heard. The vocal fremitus is diminished or lost. At a later stage, when more or less effusion has taken place, the signs of air and fluid in the pleural cavity present themselves—namely, dullness below and hyper-resonance above—in varying proportions, and shifting in relative position with the posture of the patient. If the amount of fluid be moderate, a splash or succussion-sound may be elicited. This sound may be audible to the ear applied to the chest, or to bystanders. If the fluid effusion be considerable, intercostal fluctuation may be felt; and this fluctuation gives to the finger, on percussion at the level of junction of air and fluid, a peculiar sensation of thrill. The position usually assumed by the patient now is with the head raised, and leaning towards the diseased side.

DIAGNOSIS.—The diagnosis of perforation of the lung is to be made from other diseases; and also with respect to the probable nature of the opening, and the degree of pressure present. If the three essential signs of pneumothorax be remembered—namely, displacement of heart, tympanitic percussion-note, and either absence of respiration or amphoric breathing—there can scarcely be any difficulty in making the diagnosis. It cannot be confounded with a bilateral disease like emphysema. The shifting resonance and dullness, the succussion-splash, with perhaps metallic tinkle and amphoric breath-sound, are signs abundantly sufficient to distinguish hydro-pneumothorax from ordinary empyema. It is sometimes very difficult to distinguish between a *localised* pneumothorax and a large thin-walled cavity in the lung, the signs being almost identical. Respecting the nature of the opening, whether valvular or free, careful auscultation will usually gain the desired information. If amphoric breathing be well-marked, it may be assumed that the opening is a free and tolerably direct one; if, on the other hand, no respiratory sound be audible, the communication with the pleura is indirect and more or less completely valvular. In the latter case the pressure-symptoms become more urgent.

PROGNOSIS.—Of course the prognosis in every case of tubercular pneumothorax is necessarily very grave, but by no means equally grave in all cases. The following considerations will guide to a correct prognosis: (a) *Nature of opening.* If the communication with the pleura be valvular, signified by the entire absence of breath-sound, and the increasing urgency of dyspnoea, the patient will die in a few hours unless relieved by paracentesis. (b) *State of the opposite lung.* If the effusion of air have occurred on the side least affected by previous disease, the case is correspondingly hopeless. If, on the other hand, we know that the lung now collapsed was previously much diseased, and if the other lung be but little affected, the duration of life may not be greatly shortened by the accident. Life is then gradually extinguished by hectic fever, and progressive disease in the opposite lung. It is by no means impossible, and probably happens more frequently than is supposed, that the opening in the pleura may close, the air become absorbed, and the case converted into one of simple empyema. In pneumothorax arising from accidental wound or injury to the lung, the prognosis depends upon the

visceral injury. The air in the pleura is absorbed with considerable readiness.

TREATMENT.—In all cases in which death is threatened by asphyxia, in consequence of air accumulating in the pleura, paracentesis with a fine trocar must be performed. This will in such cases give great relief, and may be repeated if necessary. There is a tendency for an opening, at first completely valvular, to become at a later period more patent, or possibly to close, so that it is better to operate when necessary with a fine trocar than to make a permanent opening. Rest to the affected side should be secured, as far as possible, by the application of a broad piece of strapping extending round the side to beyond the middle line in front and behind. The shock and dyspnoea are best treated by opium in repeated small doses. Stimulants may also be necessary, but opium is far more useful.

R. DOUGLAS POWELL.

LUNG, Rupture of.—Rupture of the lung is an extremely rare occurrence. Cases of so-called rupture of the lung from external violence are, for the most part, really produced by perforation or laceration of the pleura by a fractured rib. It is said that rupture of the lung may occur in whooping-cough. See LUNG, Perforation of.

LUNGS, Syphilitic Disease of.—Even in advanced cases of acquired syphilis pulmonary lesions are rare. The lungs are more often involved in congenital syphilis.

ANATOMICAL CHARACTERS.—*Gummata* constitute the most certain and unquestionable lesions of a syphilitic nature in the lungs, but they are rare. When present, they vary in number from one to many. In the latter case they are disseminated, but are stated to have a predilection for the deeper parts of the organs. In size these growths usually vary from that of a pea to a walnut, but may reach the dimensions of a large egg. They are generally well-defined, rounded in shape, and often surrounded with a fibrous capsule. In their early condition gummata in the lungs appear on section greyish or brownish-red, homogeneous, firm, and dryish in consistence. Subsequently they tend to degenerate, becoming more or less caseous, yellow, and less consistent; and they may even break down in the centre, so as to form cavities; while irregular strands of fibrous tissue may radiate into the surrounding tissue. The structure of these gummata corresponds to that of similar formations elsewhere. See SYPHILIS.

There is some reason to believe that a variety of *chronic interstitial pneumonia* is in exceptional instances due to syphilis. The result is a fibroid infiltration of the pulmonary tissue, which in its general and microscopic characters cannot be distinguished from a similar condition due to interstitial pneumonia from other causes, but the new tissue is said to be more vascular in its early stages. The affected parts are much indurated; and any bronchi which are implicated tend to become more or less dilated. The morbid condition may be distributed in various parts of the lungs, but appears to have a preference for their bases and the vicinity of their roots. It frequently originates at the surface, and penetrates thence into the interior of the lungs in the form of fibrous bands, the pleura being generally thickened and adherent, and superficial puckering and depressions being visible. In other

instances the fibrous tissue spreads from the root of the lung. Syphilitic fibroid infiltration has no tendency to caseation; but it may become the seat of ulceration or gangrene.

In connection with congenital syphilis, a peculiar condition has been described as affecting the lungs in new-born or very young infants (*syphilitic pneumonia, white pneumonia*). It assumes a more or less diffuse or infiltrated arrangement, is of variable extent, and may involve one or both organs. One lung may be affected throughout, while the other is quite free from disease. The more obvious characters are as follows: The pleura is usually unaffected. The lung is enlarged, and may be in a state of full expansion, so that its surface is marked by the ribs; it feels remarkably heavy; and at the seat of the disease is dense, firm, hard, and usually resistant, not breaking down under pressure. On section it presents a white or yellowish-white colour, being more or less bloodless; is uniform and smooth; and little or no fluid can be expressed or scraped from the cut surface. Careful examination reveals minute bands of fibrous tissue running in all directions. Microscopically the change seems to consist mainly in thickening of the alveolar walls and minute bronchi, with proliferation and desquamation. The vessels also become thickened and ultimately obliterated.

A syphilitic bronchitis and broncho-pneumonia is also described.

SYMPTOMS.—In the majority of cases syphilitic lesions in the lungs have only been discovered after death, no symptoms having occurred during life to draw attention to these organs; or they have been obscured by symptoms affecting other parts. Physical examination might possibly reveal the presence of gummata, as evidenced by localised dulness, bronchial breathing, increased vocal fremitus and resonance, and other signs of consolidation. The most significant signs, however, are those indicating marked induration of the lung from fibroid infiltration, especially if unilateral, and confined to the base or middle portion of the organ. In course of time signs of cavities might become evident, due to breaking down of gummata or to dilated bronchi. The general symptoms are those of constitutional syphilis, combined with those of phthisis. There is but little or no pyrexia accompanying the pulmonary lesions; and the progress of the case is essentially chronic. The effects of treatment may be of peculiar significance in the diagnosis of syphilitic disease of the lungs. The absence of tubercle-bacilli is considered an important element in distinguishing syphilitic disease from tubercular phthisis; the latter may, however, be grafted on syphilitic lesions.

TREATMENT.—Should syphilitic disease of the lungs be recognised or suspected, the appropriate treatment in most cases is to administer iodide of potassium freely and continuously. In some instances a mercurial course of treatment answers best; or perchloride of mercury might be combined with the iodide. It may be necessary to employ internal remedies or local applications for the relief of pulmonary symptoms. Cod-liver oil and tonics may be given with advantage for the amelioration of the general condition, in cases where such medicines are needed. The usual measures for the treatment of phthisical cases, as regards diet, hygiene, climate, open-air, &c., must of course be duly recognised, and adopted in suitable cases.

FREDERICK T. ROBERTS.

LUNGS, Tuberculosis of.—This may occur as part of a general infection (see TUBERCULOSIS), or as a local affection of the lungs. See PHTHISIS.

LUPUS ERYTHEMATOSUS. — SYNON. : *Erythème centrifuge* (Biett); *E. atrophicans* (Malcolm Morris); *Ulerythema centrifugum* (ὀβλή, cicatrix), Unna; *Granuloma erythematosum* (Jadassohn).

DESCRIPTION.—Lupus Erythematosus is a cutaneous inflammatory eruption of a special type, characterised by the evolution of more or less rounded, often rather tender, erythema-like macules or discs, or somewhat raised and infiltrated congestive patches, which tend to spread excentrically to a limited extent, and to leave a notable atrophy in their wake. The colour will vary from that of active congestion to cyanosis, according to the activity of the process, the site of the lesions, and the state of the circulation. If the congestion be removed by pressure a degree of cellular accumulation is often disclosed, sometimes of a citron tint and varying in different cases with the duration of the lesion and the depth to which the skin is involved.

The eruption evolves by a crop or crops of lesions, or by single lesions at intervals, and the tendency to evolve may cease at any time or be renewed. Exceptionally superficial and transient, especially in the acute cases, the lesions, as a general rule, tend to become permanent and fixed, or remain quiescent with periods of threatened activity under the influence of various excitants. The sites of predilection are characteristic, viz. the nose, the cheeks, and other parts of the face, the ears, the scalp, the backs of the hands, less commonly the forearms and feet, and rarely the palms. Any of these sites may be affected exclusively or in combination. By extension and coalescence a large part of the so-called 'flush-area' of the face may be covered in a 'bathing' distribution, which is sometimes seen in lupus vulgaris. Bilateral distribution and symmetry are the rule. A rare but interesting phenomenon bearing on the pathogeny is the occurrence of an acute exanthematic outburst on the sites of predilection or involving even the trunk, associated sometimes with high fever and toxæmic symptoms, and even ending in death from pleuro-pneumonia or tuberculosis.

Various *modifications* are brought about by the degree of congestion, of cellular accumulation, of scaliness, of atrophy, &c. There is not the tendency to ulceration or warty overgrowth, however, seen in lupus vulgaris. A telangiectatic variety may be met with, due to extreme vascularity and dilatation of the vessels, and another interesting and striking phase, usually seen on the face, is due to the special implication of the sebaceous apparatus, causing an orange-rind appearance, or the formation of a crust, with prolongations into the dilated ducts (*L. seborrhagicus, sebaceus, acnéique*; *Herpès crétacé*, Devergie).

ÆTIOLOGY.—Lupus erythematosus is not hereditary, not contagious, and not auto-inoculable. Very rarely commencing in childhood, or even adolescence, it is not infrequent in the adult—about thirty years on an average—and females are especially prone to it. It tends to die out in old people. The exciting cause is a passing one, as a rule, but may be continued or recurrent. It is probably not directly due to external excitants, such as sunlight,

heat, and cold, or to reflex causes, but a specific eruption of internal origin. Possibly, however, the localisation is determined by vaso-motor influence. It is admitted that the eruption is prone to occur in persons with a poor circulation, without much stamina, and perhaps enfeebled by disordered menstrual functions or otherwise, and in the subjects of tuberculosis, especially of the neck-glands. It is said to be more common in the colder northern climates. The name is derived from a certain clinical similarity of some cases to lupus vulgaris, especially on the face. Most authorities, however, consider lupus erythematosus and lupus vulgaris distinct affections, and they point out the striking morphological distinctions of typical cases, the extension by continuity, the absence of auto-infection, the usual multiplicity of patches, the special regional distribution with frequency of scalp-implication, the symmetry, the age-incidence, the different histology, the infrequent reaction to tuberculin, the absence of tubercle-bacilli, the fruitless inoculations, &c. Some authorities, however, still affirm the intimate association with tuberculosis, either regarding lupus erythematosus as a special attenuated form of tuberculosis, or as connected with it in some way as yet unexplained. The marked frequency of a family history of tuberculosis, of symptoms of past or present tuberculosis, such as enlarged glands or 'tuberculides,' and of ultimate death from tuberculosis are insisted on; although in some cases the autopsy fails to disclose any trace of such lesions. If the intimate connection with tuberculosis be admitted the toxic theory perhaps affords the most probable explanation, or the dissemination of organisms of little virulence.

HISTOLOGY.—There is a chronic inflammatory infiltration commencing about the blood-vessels, with dilatation of the lymph-channels, often thrombosis, and a secondary atrophy of the collagenous tissue and breaking down of some cells. The epithelium is, on the other hand, dry and hyperkeratotic. The inflammation does not necessarily pick out specially the plexuses of the pilosebaceous apparatus, though it may do so.

DIAGNOSIS.—Obviously *L. erythematosus* may simulate various congestive and inflammatory patches, especially about the face, but the eruption usually is more persistent, and is accompanied by atrophy of the skin. In the absence of the latter the observer can only be suspicious of persistent patches about the face. From chilblains it is distinguished by persistence through summer and winter, the covering white dry cuticle, and tendency to atrophy as distinguished from scarring. The diagnosis of an unusually infiltrated *L. erythematosus* from an erythematoid *L. vulgaris* is sometimes a very delicate matter, especially if the related lymphatic glands are involved. Acute outbursts when confluent may simulate erysipelas on the head and face, and, when disseminated over the face and upper extremities, and perhaps trunk, erythema multiforme for a time. On the scalp deep-seated redness gives place to markedly bald atrophic areas, with, for a time, a red punctuation of the follicles.

PROGNOSIS.—In view of the class of patient apt to be affected with this eruption, and of its possible association with tuberculosis, the outcome is not entirely free from anxiety. For the rest, the eruption is one of the most intractable with which we have to deal, though it may disappear spontaneously

or remain quiescent, or on occasion be removed by treatment.

TREATMENT.—There is no specific internal or external treatment, and the refractory nature of the eruption is evidenced by the long list of remedies and methods put forward. A nice handling and experience are necessary.

The *internal remedies* in vogue may be classified as (1) those directed to the sustenance and building up of the health generally; (2) resolvent, as preparations of mercury and iodine; (3) vaso-motor, as quinine in large doses, salicin, salicylate of sodium, ichthyol, ergot, alkalis, and ammonium carbonate; (4) empirical, as arsenic and phosphorus.

Local treatment is of prime importance, and must vary according to the conditions present. All exposure to external irritation must be avoided. It is a rule not to irritate active patches, but to apply soothing and drying remedies; under such treatment the eruption sometimes disappears or remains quiescent and comparatively inconspicuous, and with this condition of affairs some patients are content. Among such remedies may be mentioned zinc oxide, calamine, bismuth oxychloride, terra silicea, starch, acetate of lead, &c., used in powder-form, such as Unna's pulvis cuticolor (zinci oxidi, boli rubræ, boli albæ, āā 2'0; magnes. carb. 3'0; amyli oryzæ, 10'0); calamine lotion, lead lotion, black wash, Dühring's zinc-sulphide lotion (zinc sulphate, potassium sulphide, āā gr. xxx; alcohol, 3 iij; rose-water, 3 iijss), and Boeck's liniment. When the eruption is quiescent or fixed we may proceed to try more powerful astringents or resolvents of different strengths, in the form of pigment, plaster, or paste. As examples may be mentioned oleate of mercury (3-5 per cent.), daily frictions with flannel dipped in Hebra's spiritus saponatus kalinus (2 parts soft soap in 1 of methylated spirit), to which tar may be added; emplastrum hydrargyri, the French *sparadrap rouge*; Unna's zinc-sulphur-paste, with the addition of ichthyol or cinnabar. The compressing effect of collodion is often useful, and to it many drugs may be added, as 10 per cent. ichthyol or 10-20 per cent. soft soap. Oxidised pyrogallol and chrysarobin are also recommended by Unna. A strong treatment at night is often usefully balanced by a soothing day-treatment.

Should these means prove unsuccessful and the patient demand further treatment, we are left with a choice of destructive remedies, viz. caustics, such as pure carbolic acid, ethylate of sodium, strong preparations of resorcin and pyrogallol, Schutz's arsenical treatment, acid nitrate of mercury, delicate puncturing or stroking with a fine cautery, multiple scarification. It must be remembered, however, that these measures produce scarring in addition to the atrophy left by the disease, and such scarring may be more disfiguring than the eruption partially concealed by appropriate cosmetics.

LUPUS VULGARIS.—See SKIN, Tuberculosis of.

LYMPH (*lymp̄ha*, water, lymph).—Physiologically, lymph signifies the fluid which circulates in the lymphatic system. Pathologically, the term is still occasionally and incorrectly applied to the coagulable exudation which escapes from the vessels in inflammation. The name 'vaccine lymph,' or 'lymph,' is also given to the fluid con-

tained in the vaccine-vesicle. See INFLAMMATION; and VACCINIA.

LYMPH-SCROTUM.—See FILARIASIS.

LYMPHADENITIS (*lymp̄ha*, lymph; and *adenitis*, inflammation of a gland).—Inflammation of lymphatic glands. See LYMPHATIC GLANDS, Diseases of.

LYMPHADENOMA.—SYNON.: Hodgkin's Disease; Anæmia Lymphatica (Wilks); Fr. *Adénie* (Trousseau); *Lymphadénie* (Ranvill); Ger. *Pseudo-leukämie* (Wanderlich).

DEFINITION.—A disease characterised by more or less widely spread enlargement of the lymphatic glands, frequently accompanied by enlargement of the spleen, and progressive anæmia.

ÆTIOLOGY.—Very little is known of its causation. It occurs at all ages, but is more frequent in early and late adult life, being relatively uncommon between the ages of forty and fifty. Though intemperance, mental depression, insufficient food, over-exertion, exposure to cold, parturition, or febrile diseases, have occasionally been noted as antecedents, no one of these has occurred sufficiently often to be regarded as an adequate factor in its causation. The exciting cause which has been noted most frequently is some local irritation, as of a decayed tooth, discharge from the ear, sore throat, inflammation of the lachrymal sac or eczema. In these cases the glands nearest the source of irritation first enlarged, and then more distant ones were affected.

ANATOMICAL CHARACTERS.—The several groups of glands are affected in the following order of frequency, beginning with those most commonly diseased: cervical, axillary, inguinal, retro-peritoneal, bronchial, mediastinal, mesenteric. Subsidiary adjacent glands are often enlarged together with the chief groups; and nodular growths, similar to enlarged glands, arise in the course of the lymphatics in places in which the existence of glands is not usually recognised, so that continuous chains of nodules connect the various groups. The size attained by the glands in lymphadenoma varies from that of a bean to that of a hen's egg. At first the individual glands are separate and movable one on another. Ultimately they often unite to form a conglomerate mass, in consequence, in most cases, of the perforation of the capsules of the glands by growth, which may also invade adjacent parts. The cervical glands are usually enlarged in both the anterior and posterior triangles; and the submaxillary glands may encircle the neck beneath the lower jaw. They may press on the trachea or larynx, displace the latter, compress the internal jugular vein, and cause paralysis of the recurrent laryngeal nerve. The occipital glands are usually also enlarged. The axillary glands often form a mass of very large size, and prolongations may extend beneath the pectoral muscle. The glands in the anterior mediastinum frequently suffer, and the growth may extend to adjacent structures, such as the pericardium, which may be perforated. The thymus may be involved, secondarily or primarily, or may escape. The bronchial glands are diseased more frequently than the cardiac glands, and the trachea and bronchi may be pressed upon, or the lung invaded. The retro-peritoneal glands often form a mass of large size, which may surround and compress the solar plexus, causing symptoms similar

to those of Addison's disease. Enlargement of the mesenteric glands is neither common nor considerable. The inguinal group is frequently diseased, and the femoral vessels and crural nerves may be thereby compressed.

The consistence of the enlarged glands may be either soft or very hard. Usually the longer the enlargement has existed, the firmer are the glands. Their section is more uniform than in health. The colour is yellowish or whitish-grey. In the firmer glands dense tracts of fibrous tissue are seen to pass in different directions. Rarely the follicles have a different appearance, being opaque and yellowish from fatty degeneration, while the septa are white and conspicuous, from fibroid thickening. Caseation is, however, rare, and when it occurs is commonly confined to one or two glands. The softer glands yield a juice on scraping; the firmer glands yield no juice. In the former, the only histological change is an enormous increase in the cellular elements—the lymph-corpuscles of the reticulum; but the relations of the septa and follicles often remain normal. Sometimes the cell-growth invades the septa, which become split up and disappear; and it may even, in a similar manner, perforate the capsule. The firmer glands present much fibrous tissue, which may be confined to the septa, or invade also the delicate network in the substance of the gland; and then the cells gradually disappear, and the whole substance of the gland may be transformed into a fibrous mass. The tracts of fibrous tissue may have under the microscope a peculiar vitreous aspect, especially around the arteries.

The spleen is diseased in at least four-fifths of the cases, usually in consequence of disseminated growths, often irregular in shape, arising from the Malpighian corpuscles, yellowish or greyish-white, rarely caseating, and usually corresponding in consistence with the glands in the same case and resembling them in structure. The splenic pulp may be normal in quantity, or may be compressed and atrophied. In some cases it is increased in quantity, and this increase may even be the sole change. The size attained, in the cases of nodular growths, is not great, the weight being from ten to thirty ounces. When the splenic pulp is increased, the size attained is rather greater. In the latter case the enlargement is uniform, while it may be irregular when there are growths. The medulla of bones has been found, in rare cases, to present a change similar to that met with in splenic leucocythæmia and pernicious anæmia. Collections of adenoid tissue elsewhere often undergo changes similar to that of the lymphatic glands. The tonsils, the mucous membrane of the pharynx, the œsophagus, the stomach, and the large and small intestines, may all be the seat of growths, originating in the follicular glands, and sometimes ulcerating. The liver is often the seat of scattered lymphoid growths, usually minute, varying in size from a pin's head to a small pea. They occupy the interlobular spaces. Rarely larger nodular growths are found. In other cases the liver is simply congested. Similar minute growths are often found in the kidneys, chiefly in the cortex; and these organs may also be the seat of parenchymatous degeneration. The peritoneum may be inflamed over enlarged glands, or may be the seat of growths. Growths have also been found in the testicles; and frequently in the lungs, where they may break down and form cavities.

SYMPTOMS.—The most important symptoms of lymphadenoma are due to the enlarged glands and to the altered blood-state. The earliest symptoms are commonly due to enlargement of external glands, especially the cervical. When the internal glands are primarily affected, pain and pressure-signs may precede other symptoms. Occasionally the signs of anæmia precede those of the local change; and, in rare instances, irregular febrile disturbance may occur before the glandular enlargement. The affected glands are smooth, and present, at first, a peculiar mobility, which may disappear when they become adherent, and constitute an irregular lobular tumour of some size. They are usually painless, except during periods of rapid growth. A diminution in size has been observed before death. The enlargement of the cervical glands may cause the neck to equal, or even exceed, the head in circumference. The pressure on the veins may cause symptoms of passive cerebral congestion. The larynx may be displaced; and the movements of the lower jaw may be interfered with. Pressure on the trachea, by the glands in the neck and in the posterior mediastinum, may cause dyspnoea and even death by suffocation; that on the pharynx and œsophagus may obstruct deglutition, and cause death by starvation. The enlargement of the axillary and inguinal glands may interfere with the movement of the limbs, and impede the circulation. Various and serious pressure-effects result from the enlargement of the thoracic and abdominal glands, obstruction in veins, pressure on nerves, &c. The enlargement of the spleen can usually be readily felt. Earlier or later anæmia becomes pronounced. The red corpuscles may be reduced to 60, 50, or 40 per cent.; the hæmoglobin is diminished to a still greater extent (chlorotic type); and in severe cases poikilocytes and nucleated red cells (normoblasts) are seen. The leucocytes are generally not increased, but a moderate leucocytosis occasionally occurs, the white cells being mostly of the polymorphonuclear kind (*see* p. 156). The liver may be enlarged from the disseminated growths, and from congestion. Jaundice only occurs from the pressure of enlarged portal glands upon the bile-ducts. Ascites may be due to similar pressure, or to the blood-state, being then part of general dropsy. The function of the kidneys is rarely affected. Stomatitis, sometimes ulcerating, results from the lymphoid growth in the mucous membrane; and a similar change in the stomach causes interference with digestion and vomiting—symptoms which are increased by the anæmia. Slight dyspnoea results from the blood-state, while intense difficulty of breathing, and even actual suffocation, may occur from the pressure of enlarged glands on the trachea or bronchi. The functions of the nervous system are variously deranged by the ill-nourished blood. Towards the end there may be convulsions, delirium, and coma. Pyrexia is a frequent, but not invariable, symptom. It is almost always present in early life, much less common at advanced ages. The temperature may be considerably raised, even when the glandular enlargement is slight; the elevation varies from two to six degrees, and may be continuous, or with daily remissions, or periods of considerable elevation may alternate with periods in which it is only slightly raised.

COMPLICATIONS.—The pressure-effects of the enlarged glands, already mentioned, are sometimes so considerable as to give rise to complications,

such as thrombosis in vessels, pleural and pericardial effusions, and bronzing of the skin from disease of the solar plexus. Intercurrent affections occasionally met with are Bright's disease, pneumonia, fatty degeneration of the heart and liver, erysipelas, pemphigus and boils.

COURSE AND DURATION.—Lymphadenoma may remain local for a long time, even years, affecting one group of glands only, and subsequently slowly becoming general. When the general enlargement of glands is established, the disease rarely lasts more than two years. It usually terminates fatally by asthenia; but not rarely by some secondary effect of the morbid process, as asphyxia, starvation, or diarrhoea; or by a complication, especially by pneumonia.

PATHOLOGY.—The changes in the glands in lymphadenoma resemble, in the early stage, those which result from simple irritation. The nature of the disease is still very uncertain. It has often been compared with malignant disease, but in our ignorance of the nature of the latter the full value of the comparison is not obtained. The probability of its being in some way infective is very great. This view is supported by the frequency with which the first appearance of glandular enlargement follows a local irritation in its immediate neighbourhood, and by the manner in which the lesion remains for long periods confined to one group of glands, and afterwards rapidly becomes generalised not only in glands but in all lymphoid structures. Microscopical and bacteriological researches have not, however, as yet yielded any final results. The resemblance between some cases of lymphatic leucocythæmia and cases of Hodgkin's disease is very close in every point except the condition of the blood, and some authorities, regarding leucocythæmia as only an accident in the history of lymphadenoma, would include lymphatic leucocythæmia under Hodgkin's disease. But it is more common to accept, as the feature which distinguishes Hodgkin's disease from leucocythæmia, the absence of any leucocytosis, other than the moderate increase of polymorphonuclear cells, which occurs in inflammatory and other febrile conditions. See p. 156.

DIAGNOSIS.—The early stage of lymphadenoma is generally the most difficult to recognise with certainty: that is, when one group of glands is alone affected, remains stationary for weeks or months, and is unaccompanied by a sufficiently pronounced anæmia. Tubercular enlargement is generally confined to a single group of glands; it occurs in young people, and the glands caseate and suppurate; whereas the glands of lymphadenoma rarely caseate, and then probably form a secondary tubercular infection. Cancer may resemble lymphadenoma; the glands harden earlier; and secondary deposits are not so likely to take place in other glands as in internal organs. Syphilis sometimes causes a general enlargement of the external glands, which, combined with some anæmia, may suggest Hodgkin's disease. The glands are generally smaller and the condition more quickly generalised in the former disease.

PROGNOSIS.—When lymphadenoma is widely spread, or the local growths are considerable in size, a fatal termination is almost certain. The younger the patient and the better the preceding health, the longer is the duration of the disease. The consistence of the glands has little prognostic value. The softer they are, the more rapid is the

course of the disease; but, on the other hand, if it is influenced by remedial agents, the soft glands can be restored to a better functional condition than the hard. The prognosis is worse the more profound the anæmia. Elevation of temperature as a rule indicates a rapid course, but to this there are some striking exceptions.

TREATMENT.—The possibly infecting influence of the primary glandular enlargements has led to their extirpation. Where other glands have been involved, or the spleen has been enlarged, the operation has done no good; and, in such cases, surgical interference is only justified by impending death from local pressure. But where the affection has been confined to one group of glands, the progress of the disease has been retarded by their removal, and in some cases the malady has even been cured. An operation should not be performed if the proportion of red corpuscles is less than 60 per cent. of the normal. Other methods of local treatment have been employed, with some benefit, especially rubbing and shampooing, the alternate application of heat and cold, compression, and blistering. Of internal remedies arsenic is incomparably the most potent. It should be pushed to the largest doses the patient can bear, such as mxv . of liquor arsenicalis three times daily. It often causes some pain in the glands, followed by their diminution in size, and even, in a few recorded cases, by their complete disappearance. Phosphorus has been given in the disease, but it is far less useful than arsenic. Cod-liver oil may be used when there is any evidence of a scrofulous diathesis. Iron, useless alone, has sometimes appeared to do good when given in conjunction with other remedies. Of late years the animal extracts have been employed, but with no material success. Bone-marrow of the ox, from the fact that the marrow is sometimes involved in Hodgkin's disease, and from its occasional value in pernicious anæmia, may be tried in quantities of one ounce daily. Some assistance may be derived from change of air, general tonics, and careful dieting.

FREDERICK TAYLOR.

LYMPHANGIECTASIS (*lymp̄ha*, lymph; and *angiectasis*, vascular dilatation).—Lymphatic varix, or varicose dilatation of lymphatic vessels. See LYMPHATIC VESSELS, Diseases of.

LYMPHANGITIS (*lymphanḡeion*, a lymphatic vessel).—Inflammation of lymphatic vessels. See LYMPHATIC VESSELS, Diseases of.

LYMPHATIC GLANDS, Diseases of.—I. Acute Inflammation. — **SYNON.**: *Lymphadenitis*.

ÆTIOLOGY.—*Strain*, as in lifting weights, or overwalking, is sometimes alleged as the cause of inguinal lymphadenitis, and no point of infection is discoverable. It is difficult to see how strain can prejudicially affect these glands, and the effect can be only predisposing to suppurative inflammation. Possibly infection through the blood may occur.

Deposit of *organisms*, usually pyococci, in the lymph-channels of the gland is the commonest cause. As a rule the organisms are arrested in the peripheral spaces into which the afferent lymphatics open. An infected lesion is almost always discoverable in the lymph-area supplying the gland. The specific unknown virus of the *chancroid* and the *Bacillus pestis* are other causes.

MORBID ANATOMY.—An acutely inflamed gland is considerably swollen; its capsule is tense and purplish. Its surface on section bulges, is of purplish tint, less translucent than natural, and may show hæmorrhages; its substance is more friable and more succulent than natural. If suppuration is beginning, one or more yellowish points will be seen, usually in the cortex; these increase in size, run together, and ultimately fill the capsule which adheres to surrounding parts. Infection of the tissues around such a gland may occur early or late, and a periadenitic abscess be formed. Into the cavity of this a gland may project.

SYMPTOMS.—These are pain and the rapid swelling of one or more glands, the outline of which soon becomes indefinite owing to periadenitic infiltration and possibly suppuration. If pus forms the skin thins, reddens and bursts, as over any other 'pointing' abscess.

DIAGNOSIS.—After the swollen gland has ceased to be felt, this depends on the signs of an acute inflammation starting in the situation of a gland. The discovery of a primary focus of infection affords additional evidence.

TREATMENT.—This consists in giving rest and applying fomentations to the gland, and in disinfection and suitable treatment of the focus whence infection started. If pus forms a free and early incision should be made, the opening be lightly plugged with gauze, and the fomentations continued. If the patient is anaesthetised, removal of the shell of a suppurating gland will hasten healing. A gland in the centre or wall of a periadenitic abscess should be removed. The quickest way to deal with long persisting sinuses after glandular abscess is to slit up the channels and to remove the remains of the glands to which they lead. If densely fibrous, the walls of the sinuses should be dissected out or cut quite through in two or three lines.

2. Chronic Lymphadenitis.—**ÆTIOLOGY.**—

(1) Slight chronic irritation, such as proximity to a focus of chronic suppuration, renders glands somewhat large, hard and pigmented. (2) Syphilis in all its stages causes glandular enlargements—hard, discrete, rarely reaching any size or causing trouble in the primary or secondary stage; but in the tertiary, gummata of mediastinal and other internal glands may rarely form masses which produce serious pressure-symptoms (*see* BRONCHIAL GLANDS; and MEDIASTINUM, Diseases of). (3) Infection with tubercle-bacilli is the commonest cause of chronic lymphadenitis. In infancy the bronchial and mesenteric glands are most commonly affected, the virus usually reaching them from the pulmonary and intestinal mucosæ respectively. In childhood and later life the cervical glands are much more often affected than the other superficial glands. Carious teeth, tonsils, eczema and sores about the scalp and face and the middle ear, are all suspected as sources whence the bacilli have reached the glands; but in the great majority of cases no history of any lesion likely to have been the source of infection can be obtained. Either the bacilli enter through the mucous membrane without exciting any local trouble; or, having entered at some distant place, are carried by the blood to the glands.

MORBID ANATOMY.—Tuberculous glands are moderately enlarged; one the size of a walnut is exceptional. The connective tissue round about them is usually dense, and the connection between

it and the capsule of the gland closer than normal (*periadenitis*). On section, the surface of some glands becomes markedly convex, is of pale pink colour and softer than normal. Microscopically these glands show early fatty degeneration of the giant and other cells. To the naked eye caseation in smaller or larger patches is usually visible, and often the whole gland right up to the capsule is converted into a friable, opaque, pale-yellow mass. This often softens into a thick white cream or a thin curdy pus which slowly makes its way to the surface. Calcareous granules, or considerable masses of calcified cheesy material, are not rare. Sometimes the tissues round the gland become infected and a periadenitic abscess results.

SYMPTOMS.—Not uncommonly tuberculous glands swell up somewhat acutely at the start and then shrink, but do not disappear. In the great majority of cases, however, the enlargement begins insidiously and the glands are discovered by accident. Their course is very variable and is much influenced by the general health. Under favourable conditions, many swollen tuberculous glands, even of considerable size, subside and may disappear; but an intercurrent illness will often lead to rapid increase. For years small, hard, discrete glands may stud one or both sides of a neck; then, without obvious cause or in connection with some depression of health, one or more glands enlarge, soften, lose their outline owing to œdema and infiltration of surrounding tissues, and give rise to pain. Slowly the skin reddens, darkens and thins over it, and finally the abscess bursts, leaving one or more sinuses surrounded by thin blue edges. After months or years, during which dense fibroid thickening of the surrounding tissues occurs, and after more or fewer temporary cessations of discharge and closure of the orifices, healing takes place by a prominent red puckered and unsightly scar. Only one gland may be affected, and it may never suppurate; or one or both sides of the neck may be deformed by the rounded lobulated masses. They may appear also in one or both axillæ, and much more rarely in the groins. In some cases the tendency is towards caseation and drying; in others abscess after abscess forms. Other manifestations of tuberculosis may be present; but a considerable majority of cases of enlarged glands fail to produce pulmonary or general tuberculosis.

DIAGNOSIS.—It is impossible in many cases of slight chronic enlargement of the lymphatic glands to ascertain definitely whether they are due to tubercular or some less progressive form of infection. A history and other signs of tuberculosis, slow course, limitation to one region, tendency to soften, tendency to become fixed by periadenitis, absence of marked and progressive anæmia, of tendency to lethargy, of wasting and of fever, are all in favour of tubercular infection as opposed to lymphadenoma. A somewhat rapid course, a tendency to spread from gland to gland, and from one group to others, considerable enlargement of glands without any signs of softening or of fixation by periadenitis, marked anæmia, possibly leucocythæmia, tendency to lethargy, loss of flesh, and evening rise of temperature, are in favour of lymphadenoma. But the diagnosis between tubercular infection and lymphadenoma is impossible at first. Microscopical examination of a removed gland is useful. *See* LYMPHADENOMA.

A rapidly growing tumour starting in glands, spreading quickly to other glands but not to other

groups, soon becoming fixed by infiltration of surrounding parts, adhesion of individual glands to each other with rounded lobulation of the general surface of the mass, signs of great vascularity, the occurrence of secondary growths, and rapid failure of general health, point to lymphosarcoma.

TREATMENT.—In all cases of chronically enlarged glands, general hygienic treatment is of the first importance. This consists in residence as far as possible in the open air and in a dry climate, and in the thorough ventilation of all rooms both by day and night. As a rule the windows should be always kept open, draughts being prevented by sheets of perforated zinc, lowered shutters, or some other mechanical contrivance. Woollen garments should be worn next the skin. All milk should be boiled or efficiently sterilised, and drinking-water filtered through porcelain or boiled. When the cervical glands are affected the mouth should be cleansed twice daily with a weak solution of formalin (1:500), boric acid (1:20), or chinosol (1:1200). In tubercular cases, whether operated upon or not, it may be necessary to keep patients under exceptionally favourable circumstances for very long periods in order to overcome the tendency to recurrence. In many cases such general treatment, coupled with attention to all possible primary foci, is sufficient. But when the best hygienic circumstances procurable for a given patient have failed to check the progress of the disease, removal of the affected glands and of the neighbouring apparently healthy glands for some distance around should not be postponed. The skin should never be allowed to redden, much less to thin or burst, over a gland. Very extensive operations upon one or both sides of the neck, in the course of which all the great vessels and nerves come to light, and which last two hours or even longer, are well borne, and danger to life is extremely slight. In a considerable majority of the cases dealt with by thorough operation a cure seems to be effected. In many cases more than one operation is necessary to effect this; but every now and again recurrence follows recurrence, the freest operating proving of no avail. In all cases the best hygienic conditions must be obtained and continued for months or years. It is worthy of note that incisions placed in or parallel to the creases in the skin of the neck leave scars which are much less prominent than those of wounds in the long axis of the neck; also, that it is possible to remove glands from a wide area by burrowing from a small incision. But in proportion as access is impeded does recurrence appear more probable. When sinuses are present the incisions should be planned to excise the sinuses themselves, their orifices (including all thin blue undermined skin), and the glands to which they lead. No operation is likely to succeed unless attention is paid to the last point. Often the cheesy gland responsible for the trouble communicates by means of a small easily overlooked hole in the deep fascia with the cavity which itself seems to be the whole trouble, and to be adequately dealt with by erosion; or, again, sinuses low in the neck may spring from a suprahyoid gland. All tubercular granulation-tissue lining the sinus should be removed; and rapid healing is more likely to occur if fibrous sinus-walls and gland-capsules are dissected out. When for any reason tuberculous tissue cannot be cut out, the sharp spoon must be used freely, and phenol should be applied freely to the

infected tissues left by the spoon. In such cases plugging the wound with iodoform gauze is the best mode of dressing. During operations such as these disfiguring scars, the result of Nature's cures, can often be excised and replaced by fine lines.

3. Pigmentation.—Lymphatic glands (e.g. bronchial) may become black from deposit of dark particles (*see PNEUMOCOINOSIS*). Blood-pigment is deposited in them from all serious contusions, the granules often lining the lymph-path. After tattooing some of the pigments used may be found in the nearest glands.

4. Fatty metamorphosis.—According to Stiles and some other observers many glands in the axilla become changed under ordinary conditions to masses of fat having the capsule and shape of a gland with blood-vessels entering at the hilum. Under various stimuli, e.g. cancer mammae, the fat goes and the ordinary structure of a lymph-gland reappears.

5. Amyloid disease.—This is occasionally met with in lymph-glands, rendering them pale, homogeneous, waxy, and translucent. They may be of normal size and firm, or enlarged and softer. Such glands sometimes press on structures in the portal fissure.

6. Varicose lymphatic glands (Manson).—These are seen chiefly in the groin as a result of obstruction of the thoracic duct. *See FILARIASIS*.

7. New growths.—Occasionally a single gland enlarges without marked change of structure. There are no signs of inflammation; no other glands become affected, and no general symptoms are produced. Such a swelling is sometimes called a *lymphoma*. In acute cases of *lymphadenoma* and *leucocythemia* the glands may enlarge rapidly, retaining the lymphoid structure. Many glands may be affected, and many groups may be involved. *Sarcomata* of all kinds, including *melanotic*, are said to have arisen in lymphatic glands. They pursue their ordinary course but tend to infect the lymphatic glands nearest to those in which the growth started. *Sarcomata* as a rule do not produce secondary glandular growths, but *sarcomata* of the testis, fascia lata and tonsil are marked exceptions to this rule. All *cancers* tend to produce secondary glandular growths before spreading by the blood-stream. Glands so infected are generally very hard and fixed; but when secondary to epitheliomata they not uncommonly soften, and cavities form containing a fluid like pus in which the microscope shows plenty of deformed and obviously multiplying epithelial cells.

TREATMENT.—The only treatment is removal. The advisability of this will depend upon the extent of the disease and other considerations.

STANLEY BOYD.

LYMPHATIC VESSELS, Diseases of.—As it is impossible to dissociate the diseases of the primary lymph-spaces and of the smallest lymph-channels from those of the connective tissue (e.g. erysipelas, cellulitis) in which they lie, only the diseases of the larger lymphatic vessels, with distinct walls, will here be considered. For Injuries and Diseases of the Thoracic Duct *see* THORACIC DUCT.

1. Acute Inflammation.—*Acute Lymphangitis.*—The manifestations of inflammation are seen much less frequently in the lymphatic vessels than in the glands; owing to the inability of particulate

irritants to excite inflammation until they come to rest, and to the much greater frequency with which they are deposited in the labyrinth of the lymphatic glands, than in the relatively straight channels of the vessels.

ETIOLOGY.—In the enormous majority of cases lymphangitis arises in connection with some obvious focus of infection—a wound or ulcer, an abscess (open or closed), or a patch of erysipelas—whence micro-organisms (usually pyococci, see ABSCESS; and PYOGENIC BACTERIA) have entered the lymph-channels. Arrested by some more or less accidental circumstances, they soon excite irritation and thrombosis. Rarely, the source of absorption is not evident; it may have been a mere unnoticed prick, without any subsequent local reaction. This is specially seen in dissecting and *post-mortem* rooms. The pathogeny of the lymphangitis and cellulitis which precede the development of tropical elephantiasis is not yet certain. In some cases, after subsidence of the inflammation, an indurated patch has remained in which a living adult female filaria has been found; but the subsidence of the inflammation may be held to show that the filaria alone did not excite it. Lymph-stasis seems to predispose to lymphangitis; the writer has seen six attacks of lymphangitis of a slightly swollen arm occur within a few months of a thorough clearing out of the axilla for cancer. The filaria may cause lymph-stasis, and thus facilitate ordinary infection. Lymphangitis by extension from inflamed surrounding tissues doubtless occurs, but is not recognisable clinically.

SYMPTOMS.—At first pain and tenderness are complained of along the course of the affected lymphatics; soon a broader or narrower red streak appears, or there may be several such streaks, indicating the line or lines of the inflamed vessels. These streaks do not necessarily begin at the point of infection. They are red, raised, firm, tender, and irregular in outline; and are due to perilymphatic hyperæmia and exudation. The glands to which they lead are inflamed.

The temperature rises sharply at the outset, and a rigor is not uncommon. The fever usually subsides in three or four days, but some cases run a prolonged course and, exceptionally, supuration may occur at one or more points along the track of the lymphatics.

The deep lymphatics are probably as liable as the superficial to inflammation, but the trouble cannot be certainly diagnosed from pain, tenderness, fever and swollen glands—the only symptoms. See CELLULITIS.

TREATMENT.—(1) Whenever possible, the source of absorption should be disinfected with phenol. Thorough drainage should be secured, and suitable local treatment adopted. (2) General and local rest with elevation of the affected part must be obtained. (3) Hot antiseptic fomentations should be applied. Painting the streaks with glycerin and belladonna may be beneficial. Some surgeons prefer ice to fomentations. Abscesses must be opened early. Should chronic oedema or thickening of tissues remain, douching, massage and bandaging are the appropriate remedies, though too often unsuccessful.

2. Chronic Lymphangitis.

A chronic *lymphangitis obliterans* is described as playing an important part in cases of lymphoedema and elephantiasis of unknown aetiology arising in the temperate zone.

Syphilitic lymphangitis is of little importance. It is best known and typified by the thick cord of the dorsal lymphatics, not uncommonly felt above a hard chancre on the penis.

Tubercular lymphangitis of subcutaneous vessels is somewhat rare. Slowly, during months, small lentil-like nodules form in the course of the lymphatics above some tubercular ulcer—obviously at points where the bacilli, taken up from the primary lesion, become arrested. At first these nodules cause no general symptoms and no local trouble. Gradually increasing, they infiltrate the surrounding tissues and skin, soften, burst and leave a tubercular ulcer. Early in the case the glands to which the lymphatics lead will be found enlarged.

TREATMENT.—*Syphilitic lymphangitis* needs no special treatment. In *tubercular lymphangitis* the primary focus must be excised or otherwise suitably treated. The enlarged glands and all subcutaneous nodules must be removed. As these may continue to develop for weeks after removal of the primary focus, the patient requires watching for some time. Suitable general treatment is indicated.

3. Dilatation of Lymphatic Vessels.—

SYNON. : *Lymphangiectasis*; *Lymphangiooma*.

ETIOLOGY.—1. A lymphatic vessel having more than usual to carry dilates. This frequently happens, especially in acute inflammations. Lassar showed that no swelling of a dog's foot occurred after dipping in hot water, until the main lymphatics were delivering more than eight times the normal quantity. Such dilatation causes no characteristic signs, and recovery is as a rule complete. 2. The usual cause of dilatation is obstruction, but so free is the intercommunication of the lymphatic vessels and of the lymph-spaces in the tissues that the obstruction must be very extensive, or affect trunks of the first magnitude, to produce any marked effect. The best examples of lymphatic varix are seen in lymph-scrotum and other results of filariasis (see FILARIASIS). Often in the scrotum, more rarely in the leg, small vesicles, scattered or thickly set, occur, consisting of fluid and raised epidermis; these are varicose lymphatics. When pricked or ruptured many ounces of chyle or lymph may escape (*lymphorrhagia*), the flow lasting hours, or even days, and tending to exhaust the patient. From such fistule and slighter abrasions it is probable that ordinary infections start and induce the attacks of lymphangitis and cellulitis, which seem to convert the 'lymph-scrotum,' or merely oedematous leg, into a solid elephantoid mass. But if we may judge from some of the elephantoid legs which develop in this country, inflammatory attacks do not seem essential to this change, though they doubtless quicken the thickening of the tissues, and produce the most extreme degrees of induration. In elephantoid limbs, such as occur in this country, the inner coats of both arteries and veins are much thickened and the lumina diminished; many of the lymphatic trunks are obliterated. The smaller lymphatics and lymph-spaces are of course dilated.

In spite of the frequency and freedom with which glands are removed for tubercular and malignant disease, it is unusual to see oedema result: probably because a collateral circulation was opened up gradually as the glands, subsequently removed, became blocked. When oedema does occur, it is difficult to eliminate venous thrombosis. Removal of the femoral glands, and especially of the gland and tissue in the crural canal, has seemed to the writer

very liable to produce lymph-œdema. In such cases varicose lymphatics are rarely seen. Collections of lymph may form at points where the subcutaneous tissue is loose, e.g. over the olecranon process, accompanied by many of the signs of inflammation; but an incision evacuates only an orange fluid, and a lymph-fistula may be established. The connective tissue of a part which is the seat of lymph-œdema hypertrophies slowly, and the epithelium thickens and becomes coarse.

The obstruction caused by even the most extensive tubercular affection and caseation of the glands of a part seems never to cause lymph-œdema. In malignant disease œdema, e.g. of the arm in cancer of the breast, is common, but compression of the axillary vein is probably always the chief factor in its causation. The effect of plugging the glands and the lymphatics of the skin and subcutaneous tissue with cancer-cells must, however, be considerable, in proportion as the obstruction is widespread.

In certain congenital affections, of which macroglossia and macrocheilia are the best known, the part affected is enlarged, and its connective tissue is increased. Dilated lymphatics may be visible to the naked eye. In macroglossia the surface of the tongue is coarse and warty from enlarged papillæ: microscopical examination will show them to be occupied largely by dilated lymphatics. Proof of physical obstruction to the return of lymph in these cases is usually lacking. By some pathologists these and similar formations are regarded as tumours—*cavernous lymphangioma*. In more than one instance macroglossia has been associated with *cystic hygroma* of the neck. See CYSTIC LYMPHANGIOMA.

There are also recorded a few cases resembling diffuse hypertrophy or excessive development of the subcutaneous tissue, always congenital, but sometimes growing faster than the rest of the limb. On removing the mass, numerous small openings have been visible in the fat, and under the microscope the structure of a cavernous lymphangioma has been revealed. These 'tumours' are vague in outline, are not compressible, like nævi, and show none of the bluish or purplish tint of hæmangioma; they closely resemble diffuse lipomata.

TREATMENT.—In the slighter forms, elevation, massage, and bandaging are the remedies; in the more severe, excision of parts, with careful suture both of the deep tissues and of the skin to prevent leakage and promote union, thus avoiding a subsequent fistula. Asepsis is most important, as there is a predisposition to infection. In the most severe cases removal of the part may be necessary to rid the patient of an encumbrance.

For the treatment of cystic hygromata see CYSTIC LYMPHANGIOMATA. STANLEY BOYD.

LYMPHOCYTES.—See BLOOD, Morbid Conditions of.

LYMPHOCYTHÆMIA.—See LEUCOCYTHÆMIA.

LYMPHOMA.—See LYMPHADENOMA.

LYMPHORRHAGIA or **LYMPHORRHŒA** (*lymphæ*, lymph, from *λύφω*, water; and *ῥήγνυμι*, I burst forth, or *ῥέω*, I flow).

DEFINITION.—These terms literally signify a flow of lymph, but they are used to indicate an abnormal discharge from any part of the absorbent system, whether it be of lymph or of chyle.

ÆTIOLOGY AND PATHOLOGY.—Lymphorrhagia may be due to a wound affecting either the thoracic duct, the larger lymphatic trunks, or the glands. A discharge of lymph has in rare instances followed even a slight wound, particularly in the neighbourhood of joints, and this has been attributed to a constitutional defect—a *lymphorrhagic diathesis*, corresponding to the hæmorrhagic diathesis. Idiopathic lymphorrhœa is almost always the result of dilatation of one or more vessels, which ultimately rupture. They are often greatly distended before they give way. See FILARIASIS.

SYMPTOMS AND EFFECTS.—Should an escape of lymph take place upon any part of the surface of the body, it differs much in its quantity and characters in different cases. It may be less than an ounce, or amount to five and even ten pounds within the twenty-four hours; while in the same case its quantity is liable to variation from time to time, and the flow has even been known to assume a periodic character, increasing during the period of digestion. In traumatic cases the discharge either presents the ordinary appearance of lymph, being clear and limpid, or it is mixed more or less with blood or with inflammatory products. When rupture takes place spontaneously after dilatation of the vessels, the fluid is more like chyle, being more or less milky and white, from the presence of particles of fat, but its characters are liable to alter from time to time. It contains a variable quantity of fibrinogenous elements, and is proportionately disposed to coagulate spontaneously. Internal lymphorrhagia is attended with different results. In the case of the intestines and urinary organs the fluid is discharged with the fæces and urine respectively, in the former case being supposed to give rise to fatty stools, and in the latter to chyluria. Bradley attributed some cases of effusion into serous cavities, such as certain forms of hydrocele, hydrocephalus, pleuritic effusion, and ascites, to a lymphorrhagia into the respective cavities; and the writer and other observers have met with cases of ascites which seemed to support this view. Fatal peritonitis has resulted from the entrance of chyle into the peritoneum, owing to the rupture of a dilated receptaculum chyli. The escape of lymph or chyle out of the system tends to affect the general health, and, if it is in large amount, this is likely to lead to marked emaciation, debility, and anæmia.

TREATMENT.—In external lymphorrhagia all that can be done is to check the flow of lymph by pressure of bandages and the application of astringents. In cases where it takes place into internal passages, tincture of perchloride of iron in full doses may be of service.

FREDERICK T. ROBERTS.

LYPEMANIA (λύπη, grief; and *μανία*, madness).—The name applied by Esquirol to the form of insanity characterised by mental depression, usually called melancholy. See MELANCHOLIA.

LYSIS (λύω, I dissolve).—This word is now generally applied to the gradual decline of fever. See FEVER.

LYSSOPHOBIA (λύσσα, madness; φόβος, fear). A term applied to a combination of symptoms presenting superficial resemblance to hydrophobia. See HYDROPHOBIA.

M

MACROCHEILIA (*μακρός*, great; and *χείλος*, the lip).—A condition, usually congenital, in which the lips are hypertrophied.

MACROCYTE (*μακρός*, great; and *κύτος*, a hollow).—A form of large red blood-corpuscles met with in some kinds of anæmia. *See* BLOOD, Morbid Conditions of.

MACRODACTYLIA (*μακρός*, great; and *δάκτυλος*, a finger).—Hypertrophy of one or more fingers, either congenital or developing in childhood.

MACROGLOSSIA (*μακρός*, great; and *γλῶσσα*, the tongue).—Fr. *Macroglossie*; Ger. *Zungenverfall*.

The term 'macroglossia' is applied to an enlargement of the tongue, which sometimes goes to the extent of protrusion of the organ from the mouth. This affection seems to depend on dilatation of the lymphatics, with lymph-stasis, leading to hyperplasia of the connective and lymphoid tissues. It is sometimes associated with idiocy or imbecility. The cause of the lymphangiectasis, which is probably the fundamental condition, is undecided. *See also* TONGUE, Diseases of.

MACROSOMATIA (*μακρός*, great; and *σῶμα*, the body).—Fr. *Macrosomatie*; Ger. *Riesenwuchs*.—A condition in which the whole body becomes enlarged in a monstrous degree. *See* HYPERTROPHY.

MACROSTOMIA (*μακρός*, great; and *στόμα*, the mouth).—A congenital enlargement of the mouth, due to imperfect closure of the mandibular fissure upon one or both sides. It is a rare deformity, and is generally accompanied by malformation of the auricle, by an accessory tragus, or by a mandibular tubercle. Excessive closure of the mandibular fissures may also occur, leading to *microstoma*.

MACULÆ (*macula*, a spot or stain).—SYNON. : Fr. *Macules*; Ger. *Flecke*.

Maculæ are spots or small stained areas due to localised pigmentation, hæmorrhage, or inflammatory exudation, in or beneath the skin. Sunburn, freckles, bronzed and melasmic spots, and the stains left on the skin after the dispersion of certain cutaneous eruptions, such as psoriasis, acne, lichen planus, syphilis, and leprosy, are examples of maculæ.

MADEIRA, North Atlantic Ocean.—Moist, mild, equable climate; absence of dust; well protected.—Mean temperature 61° F. *See* CLIMATE, Treatment of Disease by.

MADNESS.—*See* INSANITY.

MADURA-FOOT.—A synonym for fungus-foot of India. *See* MYCETOMA.

MAGNETISM, ANIMAL.—This name was formerly applied to an imaginary new force or principle, supposed to be akin to magnetism, and to be in operation when individuals were 'mesmerised.' This hypothetical new force was thought

to be called into play by the mesmeriser; and it was deemed to be by virtue of its influence that the will, thoughts, and actions of the 'medium,' or person mesmerised are capable of being modified in the so-called mesmeric trance or sleep. This view as to the nature of the causal conditions is now regarded as altogether erroneous and devoid of all foundation in fact, although certain remarkable effects may unquestionably be produced on many persons (by so called 'mesmeric passes,' by concentration of attention associated with some strain of ocular muscles, by attention to a series of weak monotonous sensations, or other related means), owing to the induction in such persons, under physiological conditions, of some at present imperfectly understood state or modification of cerebral activity (*see* MESMERISM). This state is now generally spoken of as the 'hypnotic condition,' 'hypnotic sleep,' or 'hypnotism'; or more rarely as 'induced somnambulism.' On the other hand, when such a state is induced, as a therapeutic means or agency, it has been spoken of as 'Braidism' (*see* BRAIDISM).

H. CHARLTON BASTIAN.

MALACOSTEON (*μαλακός*, soft; and *ὀστέον*, a bone).—*See* MOLLITIES OSSIUM.

MALAGA, in South of Spain.—Dry, mild, bracing, equable climate. Mean temperature in winter, 55° F. Winds: N.W. (*Terra*), dry and dusty; E. (*Levante*), cold and damp. Drainage and accommodation defective. *See* CLIMATE, Treatment of Disease by.

MALAISE (Fr.).—SYNON. : Indisposition; Ger. *Misbefinden*.—During the onset of acute fevers, in the course of mild digestive disturbances, and in other conditions, the patient complains of a vague ill-definable feeling of illness, accompanied by languor and listlessness. This condition is known as *Malaise*.

MALARIAL DISEASE (Ital. *mala aria*, bad air): comprising MALARIAL FEVER and MALARIAL CACHEXIA.—SYNON. : Malaria; Paludism, Marsh - Fever, Jungle - Fever, Periodic Fever, Paroxysmal Fever.

DEFINITION.—A disease caused by unicellular parasites of the red blood-corpuscles.

VARIETIES: (1) Intermittent Fever or Ague, comprising Quartan Fever and Milder Tertian Fever; and (2) Remittent or Estivo-Autumnal Fever.

SUMMARY.—The malady is characterised at the onset by a specific rhythmical fever; by destruction of red corpuscles; and by deposition of altered hæmoglobin in certain tissues. Later there is a tendency to frequent relapses; and to the establishment of a specific cachexia, of which the principal symptoms are melanosis, anæmia, and enlargement of the spleen.

The parasites are of at least three species, and belong to a group of Protozoa, of which other species are found in many vertebrates. They occupy and destroy the red corpuscles; convert the hæmoglobin into melanin; multiply indefinitely in the blood by simultaneous sporulation, which occurs

at regular periods of one, two, or three days (according to the species); produce rhythmical accessions of fever by the liberation of a toxin at the moment of sporulation; and sometimes continue to infect the patient for years. On ingestion by gnats of the genus *Anopheles*, they undergo further development in the insects; from these their spores may pass through the salivary duct into healthy human beings.

Quinine is a specific remedy at certain stages of the disease.

HISTORY.—The ancients were able to distinguish the rhythmical fevers, and to recognise their various types and their connection with the presence of stagnant water. Early in the eighteenth century Lancisi further emphasised this connection, and appears even to have suspected gnats of being associated with the disease. About the same time the discovery that cinchona bark cures the rhythmical fevers enabled physicians clearly to demonstrate the difference between these and fevers of other types; and in 1753 Torti, assisted by this discovery, first established with accuracy the symptomatology of the malarial fevers. Nearly a century later Meckel laid the foundations of our knowledge of the pathological anatomy by his discovery of minute black granules, called *melanin* or *malarial pigment*, in the blood and spleen—a discovery confirmed later by Virchow, Heschl, and Frerichs. In 1854 Planer suggested, and in 1874 Arnstein showed, that the melanin originates in the blood and is afterwards deposited in the spleen and other tissues; thus reversing the theory formerly held.

In 1880 Laveran recognised that the melanin is produced within unicellular parasites, which occupy the corpuscles and convert their hæmoglobin into this substance; and described all the various forms under which the parasites are found in human beings. In 1885 and subsequently, Golgi established the facts that the organisms multiply by simultaneous sporulation; that the accessions of fever occur at the moment of sporulation; and that different types of fever are associated with different varieties of parasites. These observations were confirmed by Marchiafava and Celli and Canalis, who also made a careful study of the parasite of remittent fever; while a number of other observers repeated and amplified all these discoveries in many parts of the world. The structure of the parasites was carefully studied, and similar organisms were found in various lower animals. Gerhardt (1880), followed by many others, produced infection in healthy persons by injection of blood from diseased subjects; and many observers, especially Laveran, Kelsch and Kiener and Bignami, carefully examined the pathological anatomy.

In 1883 King elaborated a theory that malarial disease is communicated by the bites of gnats. In the following year Laveran briefly enunciated a similar hypothesis. In 1894 Manson propounded the induction that certain forms of the parasites (gametocytes) are destined for further development in gnats; and the gnat-theory was also accepted by Koch, Bignami, and others, on various grounds. In 1897 MacCallum proved the sexual nature of the gametocytes. In 1897 and 1898 the writer, following Laveran's and Manson's inductions, ascertained the life-history of this group of organisms in gnats, found the mode of infection by inoculating a number of healthy birds by the bite of infected gnats, detected two hosts of the parasite

of remittent fever in India, and studied the habits of the insects there. These observations were almost immediately confirmed and amplified by Koch and Daniels. Bignami, Grassi and Bastianelli found the parasites in various species of anopheles in Italy, and claimed to have succeeded in infecting men. Subsequently Koch, Daniels, the writer, and other observers found the alternative hosts, and studied their habits in relation to malaria, and the modes of prevention, in various parts of the world. Daniels and Koch have also noted the great prevalence of the disease among native children in the tropics, and they, Celli, and others have studied the subject of immunity. Manson has infected healthy persons in London by means of gnats brought from Italy, and has proved experimentally that it is possible to remain free from the disease by living in a mosquito-proof dwelling.

EPIDEMIOLOGY.—1. *Distribution.*—Malarial Disease is essentially a malady of warm climates. If it occurs in temperate climates, the season of fresh infections is the summer or the autumn. As a rule its prevalence increases the nearer we approach to the equator. Broadly speaking, it exists in almost all warm countries; though, everywhere, some areas are much more malarious than others, this law often applying even to localities a few miles apart. Tropical Africa, India, the Indian Archipelago, Southern China, Central America, and the shores of the Mediterranean may be cited as being the most generally malarious regions. But the disease exists to a small extent much farther north. For example, it was formerly present in Scotland, and still occurs in Holland. Strict investigation is now showing it to abound among indigenous populations which were formerly thought to be comparatively exempt; and, in fact, the physician may expect to meet it wherever the local conditions are favourable. The total amount of sickness and mortality due to it cannot be exactly computed, but must be enormous.

Malarial Disease is essentially also an *endemic* disease: it adheres to certain localities. At the same time it is apt to increase and diminish both in prevalence and severity within an endemic area; and also to travel slowly beyond endemic areas into others where it was formerly little known.

2. *Conditions.*—Warmth, stagnant surface-water, rank vegetation, poor dwellings, and the proximity of many infected persons, are the conditions under which infection is most likely to occur. From these it follows that level or depressed ground, unabsorbent soil, rains, forests, marshes, and native villages are particularly favourable to the disease. These conditions may be general, as on the coasts of Africa; or local, as in mountain valleys, oases in the desert, or villages in the hollows of open savannahs. In the latter cases, the slopes of the hills, the desert, or the savannahs themselves may be comparatively healthy. On the other hand, cold, dry soil and atmosphere, altitude, steep surface, open country, well-built houses and cities, and a healthy population are opposed to the disease; while well-contained lakes and rivers, and cultivated vegetation are not particularly favourable to it. It must be added, however, that many localities where all malarious conditions seem to exist are singularly free from the disease.

3. *Mode of dissemination.*—Conclusive microscopical and experimental researches demonstrate that the parasites complete the cycle of their

existence in gnats of the genus *Anopheles*, which carry them from diseased to healthy persons; and that the habits of the insects—their prevalence in warm countries, their tendency to breed in surface-pools of water, and their predilection for rank vegetation—go far to explain the phenomena which were formerly attributed (without any strict, much less experimental, evidence) to a telluric influence.

Gnats, or as they are called in the tropics *mosquitoes*, belong to a family of dipterous insects named Culicidæ—a family which contains about 12 genera and 250 species. The *larvæ* and *pupæ* are aquatic. The adults possess a suctorial proboscis and scaled wings. The commonest genera are *Culex* and *Anopheles*. In the former the female has short palpi, in the latter long palpi. According to many observers there are other differences between these genera, which, though they may not always hold good, are generally very useful to the observer. Thus the *larvæ* of *Culex* have a long breathing-tube at the tail, by which they hang suspended, head downward, from the surface of the water; while those of *Anopheles* possess no elongated breathing-tube and float flat on the surface. The former *larvæ* may be found in almost any stagnant water in tubs, pots, cisterns, drains, &c.; while those of *Anopheles* prefer pools on the ground, hollows in rocks, sluggish runnels of water, and sometimes even ponds, tanks, rice-fields, and the margins of streams. The adults of *Culex* generally have a thin proboscis and a clumsy thorax, and rest on a wall with the tail almost touching it; the adults of *Anopheles* have a proboscis which appears thicker, and a straight elegant body, and rest with the tail pointed away from the wall at a varying angle. *Anopheles*, moreover, generally possess several dark marks on the anterior margin of the wings, while the wings of *Culex* are more frequently plain. The males of both genera can be distinguished by their feathered antennæ. As a rule, only the females feed on blood. Both sexes also feed on the juices of fruit. The insects may live for months, haunting houses close to the breeding-pools, or biting cattle and birds, and laying their eggs every few days. They hibernate in temperate climates.

In malarious localities a considerable percentage of *Anopheles* caught in the dark corners of infected houses are found to contain the parasites. The insects seem to become infected, as a rule, from native children, of whom, according to the observations of Daniels, Koch, and others, sometimes over 50 per cent. may harbour parasites. Stephens and Christophers observe that *Anopheles* congregate round persons camping in bush far from human habitations, and that many even of such gnats have blasts in their salivary glands. In short, all recent investigations demonstrate how easily infection must take place in localities where both *Anopheles* and cases of malaria abound.

It has not yet been absolutely demonstrated (*a*) that other kinds of gnats besides *Anopheles* do not carry the human parasites; (*b*) that the insects do not acquire the parasites from each other, or from other animals as well as from man; or (*c*) that there may not be some other route for infection. Up to the present, however, no facts which will justify any of these hypotheses have been established, and the simple observation that *Anopheles* carry the parasites from diseased to healthy persons appears to be quite sufficient to account for the dissemination

of the disease. At all events, this seems certainly to be by far the commonest way by which infection is produced.

PARASITOLOGY.—The parasites of malaria belong to a group called the Hæmamebiidæ. This group is generally placed among the Sporozoa, an order of the Protozoa or Unicellular animals. The Hæmamebiidæ contain at least nine species, of which three are found in man, one in monkeys, three in bats, and two in birds. The writer divides the group into two genera, one of which includes the quartan and tertian parasites of man and all the parasites of birds, bats, and monkeys; while the other contains the æstivo-autumnal parasite. The life-history of the human parasites is as follows:—

The youngest organisms are found as small amœboid bodies in or on the red blood-corpuscles. Each consists of a small nucleus (chromatosome) and surrounding bioplasm. The *amœbule* grow in size and convert the hæmoglobin of the containing corpuscle into melanin. They reach maturity in one, two, or three days, according to the species; and then become either (*a*) sporocytes, or (*b*) gametocytes. Among those destined to be sporocytes, the nucleus divides into a variable number of segments—each segment collecting some of the bioplasm round it and becoming a spore. When finally mature, the organism ruptures the cellular host and scatters its spores, together with a small residual mass containing its melanin, into the liquor sanguinis. The spores attack fresh corpuscles, and the melanin is engulfed by the phagocytes of the host. This constitutes the *asexual* or *fever-producing* cycle of the parasites.

The amœbulæ which develop into *gametocytes* show no division of the nuclei within man. These bodies are, in fact, sexual forms, male and female, and belong to the *sexual* or *mosquito-cycle* of the parasites. They circulate unchanged in the blood, awaiting ingestion by the appropriate second host, *Anopheles*. As soon as they are drawn into the stomach-cavity of this insect they undertake their sexual functions. They burst from the enclosing corpuscle and swell slightly. The male gametocyte now emits four or more active motile filaments, called *microgametes* and formerly called *flagella*. These are, in fact, spermatozoa. They are generally emitted from 10 to 30 minutes after the blood was drawn by the insect (they are also often emitted in an ordinary fresh microscopical specimen). After struggling for a few minutes, one or more of them break away from the parent male cell, and, after wandering about in the liquor sanguinis, enters one of the female gametocytes, fertilising it. This process has been actually witnessed by MacCallum. The fertilised female gametocyte is called a *zygote*. After a time it becomes elongated and motile, and commences to work its way through the mass of blood in the insect's stomach. Arrived at the parietes, it passes through them and fixes itself on the outer surface of the stomach. Here it commences to grow rapidly, still, however, containing its original granules of melanin. The nucleus undergoes numerous subdivisions. After at least a week, the zygote, still fixed motionless in this position, is mature. It is then found to consist of a capsule full of many hundreds of filamentous spindle-shaped bodies called *blasts* or (incorrectly) *sporozoites*. The capsule now ruptures, pouring the blasts into the body-cavity of the insect. The

blasts are carried all through the tissues by the circulation, until they arrive at the *salivary gland*, when they penetrate into the *salivary cells*. From these they pass into the *salivary duct*. This duct practically opens at the extremity of the central stylet or lancet of the mosquito's proboscis—the salivary secretion being destined to pass into the wound made by the puncture. With this secretion the blasts enter into the circulation of a fresh host, and set up a malarial infection in him, as proved by numerous experiments made by the writer, Daniels, and Koch, on birds, and by Bignami, Bastianelli, and Manson on men.

The three human species all possess this life-history, but differ in minor particulars, which enable us to distinguish them with ease.

The *Quartan Parasite* (*Hæmameba* or *Plasmodium malarie*—figs. 1-7) occupies a small or medium-sized corpuscle. Its amœboid movements are rather slow. Its melanin consists of rather coarse dark-brown granules. It produces about 8 spores. Its life-cycle lasts 72 hours. All stages can be found in the finger-blood. The gametocytes are shaped roughly like the sporocytes before the spores are formed.

The *Tertian Parasite* (*Hæmameba* or *Plasmodium vivax*—figs. 8-13) occupies a large, sometimes pale, corpuscle. Its amœboid movements are very active, the half-grown amœba being of a ragged shape, and often looking like several separate amœbæ. Its melanin consists of very fine granules, which are generally of a light-brown colour. It produces about 15-20 or more spores. Its life-cycle lasts 48 hours. All stages can be found in the finger-blood. The gametocytes are shaped like the sporocytes, but have a coarser pigment.

The *Æstivo-Autumnal Parasite* (*Laverania* or *Plasmodium præcox*—figs. 14-48) occupies a medium-sized corpuscle. Its amœboid movements are very active when it is young. The smallest forms often contain no melanin at all, but frequently take the appearance of a little ring inside the corpuscle. Later, the amœbæ form two or three masses of black pigment and retire to the internal organs. The sporocytes (which are seldom found in the peripheral blood) are rather small and produce numerous small spores. The life-cycle lasts 24 hours in the æstivo-autumnal quotidian parasite, and 48 hours in the tertian variety. Only the youngest amœbæ and the gametocytes are found in the finger-blood. The gametocytes have a special shape—that of a crescent with a mass of black pigment-granules in the centre. In the male, the granules lie separate; in the female they lie close together, often in the form of a ring. Shortly after the blood is drawn many of the crescents become oval and then spherical, and some produce flagella (spermatozoa) in from 10-30 minutes.

It should be noted that in all the species the gametocytes are not invariably present. In the quartan and tertian species they generally appear during the paroxysm, remain for a day or two, and then vanish. In the æstivo-autumnal they do not appear until the first series of paroxysms has lasted about one week; but may then remain for several weeks. In old cases of æstivo-autumnal fever, however, or in cinchonised patients, they may not be produced at all; though when they are once produced, quinine does not much affect them.

The development of all the species in mosquitoes is practically the same (figs. 35-48); but the young

tertian zygotes can generally be distinguished by their fine, light-brown pigment.

MODE OF INFECTION.—Infection is caused by the bites of gnats which contain blasts; these gnats have hitherto been found to belong exclusively to the genus *Anopheles*. Bignami states that the bite of a single infected gnat can infect man. Judging from dissections of the insects it is probable that a few thousands of the blasts suffice to produce this effect.

The question whether there may not be another route for infection has not yet been definitely settled; but, at all events, no other has actually been found.

NUMBER OF PARASITES REQUIRED TO PRODUCE FEVER.—It is a general experience that when fever is present the parasites can be found in the blood by a skilled observer. They may be extremely numerous: it is certainly not uncommon to find as many as one parasite to every fifty corpuscles. We may roughly estimate that, when fever is present, at least one corpuscle in 100,000 contains a parasite. Physiologists calculate that in the whole body of a healthy man of 150 lbs. weight there are about 25 billion red corpuscles. If one in 100,000 of these contains a parasite, there must evidently be about 250 million parasites in the whole body. This then must be approximately the least number of organisms required to produce fever.

In this estimate the gametocytes, which do not cause fever, need not be considered.

PATHOGENESIS.—To explain (a) the fever, and (b) the excessive destruction of corpuscles, which follow the sporulation of a horde of parasites, some observers have supposed that the newly produced spores irritate the thermic centres. Against this view may be set the fact that a large dose of quinine given before the paroxysm will destroy vast numbers of spores (as proved by subsequent microscopical examination), but may not modify the impending fever in the smallest degree—though it may entirely avert the *next* attack. Again, the excessive destruction of corpuscles seems to exclude the idea that the only action of the parasites on the system is a mechanical action. The theory of a pyrogenic and hæmolytic toxin (which may just possibly be connected with the freshly liberated melanin) appears to be the only theory capable of explaining the facts of the case. At the same time it must be understood that no toxin has as yet been actually isolated in malarial blood.

PATHOLOGICAL ANATOMY.—The pathological anatomy of the paroxysm depends upon (1) the deposition of melanin in certain tissues; (2) the deposition of the detritus of red corpuscles and of hæmoglobin; and (3) the congregation of æstivo-autumnal parasites in certain sites. As the paroxysms succeed each other, the melanin not only continues to be deposited but passes out of the capillaries and tends to be eliminated by the connective tissue and lymphatics. At the same time another pigment, the *yellow pigment*, is precipitated in the liver, spleen, bone-marrow, and kidneys; and the precipitation of this pigment continues after the subsidence of the parasitic invasion, and lasts during the cachectic anæmia which follows. It consists of granules of a pale or of a bright yellow colour, very small, or up to about 6μ in diameter, and of a square or angular shape. In the liver it occurs in the hepatic cells, often round the central vein, whereas the black pigment is found only in the connective tissue. In the spleen it is found in cells of the pulp; in the

kidneys in the epithelium of the tubules. It blackens with age (Bignami). Though both melanin and the yellow pigment contain iron, only the latter gives the iron-reactions with potassium ferrocyanide and hydrochloric acid, or with ammonium sulphide (p. 57). The black pigment is soluble in alkalis (e.g. ammonium sulphide), but insoluble in acids; the yellow pigment in both. Further study on all these points is required. The yellow pigment is found also in essential anæmias and even in ankylostomiasis (Daniels), and is reasonably thought to be derived from the detritus or dissolved hæmoglobin of the red corpuscles. It is probably eliminated in the bile.

Macroscopically, we have during the paroxysms pigmentation and sometimes hyperæmia of the spleen, liver, brain and meninges, marrow, and kidneys. The liver is reddish brown, enlarged and softened; the spleen enlarged, softened, and almost black. In chronic disease, the spleen may be much enlarged; its colour is variable, depending upon the degree of melanosis; adhesions are generally present. The liver also may be much enlarged, with adhesions; the colour depends upon the relative amounts of the two pigments; the lobules are marked by melanosis of their periphery. As true cachexia sets in, melanosis vanishes, leaving the previous hyperplasias. Finally atrophy and amyoid degeneration are recorded.

CLINICAL PHENOMENA.—1. *Incubation-Period.* While it is certain from experiment that the malarial parasites cause infection after entry into the human circulation, the immediate changes which they undergo at that moment have not been ascertained. It may reasonably be held, however, that they shortly enter the corpuscles and become amœbulae; and that these amœbulae next commence to reproduce themselves in the ordinary manner—gradually becoming more and more numerous until, after the lapse of a definite interval, they become numerous enough to cause illness.

The actual incubation-period has been determined (a) by infection-experiments with gnats; (b) by similar experiments with inoculation of malarial blood; and (c) by observation of persons who have been taken ill some time after spending a single night in a malarious locality. The period may be taken as being from about six to twenty days.

There are cases in which the progress of the invasion appears to be checked for a long time after infection, probably by the use of quinine as a prophylactic, or by a cool external temperature. In such cases the fever may suddenly burst forth when the patient abandons the quinine, or enters a hot climate. Instances of fever occurring a few hours after infection are apocryphal.

2. *Prodromata.*—When the number of parasites mounts up toward the number requisite to cause fever, certain premonitory symptoms may be observed. These are, briefly, aching in the bones; dull pains in the head, liver, and spleen; chilliness; and often slight rises of temperature for a day or two before the typical paroxysm occurs.

3. *The Malarial Paroxysm.*—When the parasites have multiplied up to or beyond the fever-point the catastrophe occurs. At this point the organisms, occupying the corpuscles in vast numbers, have simultaneously grown to their full dimensions, and have divided each into a number of spores. Next, almost simultaneously, the containing corpuscles of

all the parasites are ruptured; the spores, the melanin, and the toxin escape into the liquor sanguinis; and the paroxysm or ague-fit commences. This consists of the three well-known stages—the cold stage, the hot stage, and the sweating stage.

Cold stage or rigor.—The patient experiences a curious sensation of chilliness. The fugitive pains in the body increase. A sudden nausea often sets in. The chilliness rapidly augments; and if the patient rises, or if a breeze blows upon him, he begins to shiver, and then to shake all over. He is obliged to fling himself on his bed, and in the hottest weather calls for bed-clothes to be heaped over him. His teeth chatter, he lies huddled up, his lips and nails are blue, his countenance is anxious, and frequently he vomits several times. If we take his temperature, however, we find that, far from being below normal, it is already actually some degrees above it. The pulse is small and a little quicker, the respiration hurried; the urea, chlorides, and total amount of urine increased; phosphates diminished; pupils dilated; and headache, horripilation, and vertigo often present. Thayer found this stage in 97 per cent. out of 332 cases. It is more pronounced in the quartan and tertian varieties; less marked and often entirely absent in the æstivo-autumnal. The stage lasts from a few minutes to about an hour.

Hot stage.—The temperature of the blood continues to rise, and may reach its maximum about two hours after the onset of the ague-fit. As it rises, the rigor gives place to flushes of heat, until the patient now feels as hot as he formerly felt cold. Headache, vomiting, vertigo increase; the skin is flushed, the conjunctivæ injected; the pulse rapid and full; pains in the bones, cough, urticaria, jactitation, epistaxis, diarrhoea, and even delirium or drowsiness, and coma may be present. The urine becomes more scanty and high-coloured, and frequently contains albumen. The temperature often reaches 106° F. or more. Enlargement of the spleen is demonstrable in a large percentage of even recent infections; and anæmia can be already detected on counting the corpuscles. This stage is almost invariably present. It may last from one to many hours. It is much longer in the æstivo-autumnal infection than in quartan and tertian.

Sweating stage.—Beads of perspiration now begin to form on the lips, forehead, and breast. The temperature falls rapidly. The pulse becomes slower. Profuse sweating, with relief from most of the symptoms, sets in. Phosphates in the urine are augmented, the excretion of urea still remaining above the normal. The temperature continues to fall until it often goes several degrees below normal. The sweating then ceases, and the enlargement of the spleen rapidly diminishes; but more or less anæmia remains. The length of this stage may be put down at two to four hours.

The patient now feels almost recovered. The paroxysm has ceased, and the *intermission* begins.

The parasites.—If the blood be examined every hour during the ague-fit the following changes in the parasites will be observed. At the beginning of the rigor a number of full-grown organisms, each practically consisting of a cluster of spores, can be seen; and also a few very young amœbulae attached to the corpuscles, and apparently recently escaped from some of the full-grown parasites just referred to. As the paroxysm advances the mature parasites rapidly diminish in number as they break up into

free spores; while at the same time the amœbulæ become more numerous. Finally, about the height of the fever, no more mature parasites are found—all of them having broken up by this time; but the blood now contains numerous amœbulæ, each attached to or ensconced within its cellular host. During the sweating stage and all through the following intermission, the organisms grow in size, until they in their turn reach maturity and occasion a fresh paroxysm.

With the quartan and tertian parasites, all these changes can easily be followed by examining blood taken from the skin at intervals; but with the æstivo-autumnal species this is not possible, because when the amœbulæ reach a certain stage of growth they vanish from the peripheral circulation, so that the sporocytes can only be found in blood taken from the inner organs, e.g. by acupuncture of the spleen.

Besides the sporocytes and amœbulæ, we often find gametocytes—sometimes in very large numbers. These, having no marked pathological significance, do not concern us at present.

Destruction of parasites.—As each sporocyte produces from 8 to 30 spores, according to the species, the total number of the invading organisms would increase indefinitely were it not for some resistant principle in the host. We are forced to conclude that some such principle exists, but we do not yet fully understand the mechanism. If a patient be kept at rest in bed the phenomenon of *spontaneous recuperation* often occurs; the parasites rapidly decrease in numbers, and an expected paroxysm fails to appear. Phagocytosis does not suffice to explain such cases, and it is more likely that the blood fabricates some chemical agent inimical to the invaders. Quinine, if given in sufficient doses, has the same effect. The observer must never imagine, however, because the parasites have become too few for the moment to be readily found, that they have disappeared altogether.

Disposal of melanin.—The residual masses of melanin left after the dispersion of the spores are quickly taken up by (a) the wandering phagocytes of the blood, and (b) the fixed phagocytes of the vascular endothelium. The former are principally the large mononuclear leucocytes, and, to a less degree, the polynuclear neutrophils. The fixed phagocytes are endothelial cells of the spleen, cerebrum, liver, and bone-marrow. Thus every paroxysm is followed by the appearance of melanin in a vast number of cells, especially in the spleen and the splenic vein. Pigmented leucocytes begin to appear in the peripheral blood shortly after the commencement of the paroxysm.

Leucocytes during the paroxysm.—These are diminished in number in ordinary attacks. In pernicious attacks, however, they may be largely increased in number—though this is now generally attributed to some complication. *Relatively*, the mononuclear cells are increased, and the other varieties diminished, at least after the crisis.

The red corpuscles.—A certain number of these are destroyed by the breaking up of the sporocytes which they contain; but counts made before and after the paroxysm show that a large number must be destroyed by some other agency in addition. It is therefore supposed that the toxin liberated by the sporocytes is hæmolytic as well as pyrogenic. During severe paroxysms one or two million corpuscles, or even more, may disappear in every

cubic millimetre of blood. This hæmolysis is more marked in earlier than in later attacks.

Not only are the corpuscles reduced in number, but they also often lose much of their hæmoglobin. The total amount of hæmoglobin may be reduced by 50 per cent. after several paroxysms, and reparation is slow.

Other blood-changes.—The density of the blood decreases with the decrease in the number of corpuscles (Viola). The total quantity of blood is diminished (Kelsch). The isotonicity of the corpuscles is increased owing to the destruction of the less resistant cells (Viola).

The urine.—The amount of urine excreted has not been sufficiently investigated to be considered here in detail. The specific gravity tends to be increased. The colour is usually dark, especially during the fever. The phosphates decrease during the fever and increase during defervescence and during the intermission. Potassium is in excess of sodium; both are more abundantly excreted during the paroxysm than after it. The chlorides are in excess during the first stage of the paroxysm, and diminish at the crisis and afterwards. Iron is considerably increased, especially after the attack. The amount of urea is increased; it is greatest during the first stage, and least after defervescence. The uric acid seems to be unaffected. Albuminuria, hæmaturia, and glycosuria occur in some cases. Experiments on the toxicity are not conclusive.

Other facts.—The tongue is generally small, red, and clean during the first paroxysm; later it may become coated, especially in severe cases. The bowels tend to be constipated. A marked increase in the area of splenic dullness can generally be detected, even after the first paroxysm. Splenic, hepatic, or epigastric tenderness is often present. Marked pallor, indicative of the rapid hæmolysis, frequently occurs after the attack.

Modifications in the paroxysm.—The paroxysm as described above is subject to modifications which may be divided for clinical convenience into (a) normal, and (b) abnormal modifications. The most important of the first are the modifications due to the species of parasite concerned.

The quartan paroxysm.—This lasts about 9 hours. The premonitory symptoms are generally slight. The rigor is usually severe and distressing, and is seldom absent. The fever is sharp, rising to 105° or 106° F., or even more. The sweating is profuse and gives rapid relief.

The tertian paroxysm lasts about 11 hours, and is very like the quartan. The rigor is perhaps less severe, the fever more so, secondary symptoms such as vomiting, headache, and pains in the bones being perhaps more marked.

The æstivo-autumnal quotidian paroxysm is generally short, lasting 6 to 12 hours (Marchiafava and Bignami). Rigor is very often slight or absent; but the secondary symptoms are apt to be very severe.

The æstivo-autumnal tertian paroxysm is the gravest and longest of all. It lasts from 24 to 40 hours (Marchiafava and Bignami). The temperature-curve differs much from that of the other varieties. There is a rapid and high rise, followed by sustained fever, and then by a temporary fall with some amelioration of the symptoms—called the *pseudo-crisis*. But the fever now increases again, rising still higher than before; and, lastly, the true crisis sets in. The secondary symptoms are most severe

in this variety; pernicious attacks most common; and, perhaps, rigor most often absent.

Other normal modifications.—It must always be remembered that the paroxysm is likely to be most prolonged and severe in *earlier attacks*, to whatever species of parasite they are due. In such cases the *prolongation* is often caused by the fact that as a rule in recent infections the parasites do not sporulate so simultaneously as they do later. At the same time the severity of the symptoms is greater, probably because the patient, who is as yet unaccustomed to the disease, is more sensitive to the intoxication. Hence it often happens, even in certain cases of tertian or quartan, that the paroxysm is so prolonged that before it is well over the succeeding paroxysm has already commenced, giving rise to a *remittent* or *subintant* fever.

On the other hand, in old infections just the opposite state of things prevails: the parasites tend to sporulate smartly together; and the system, better inured to the toxin, suffers less severely from its effects. This is frequently seen in natives of malarious districts, especially in native children. In such the paroxysm is often scarcely apparent: the adult lies down for half an hour, and the child continues to play undisturbed.

Other points to be remembered are that the severity of the paroxysm depends *ceteris paribus* (a) on the number of sporocytes present, and (b) on the species—the æstivo-autumnal being the most virulent.

4. *Pernicious Paroxysms.*—In addition to the variations of the paroxysm just given, which may be looked upon as being more or less normal incidents of the disease, certain exceptional forms, of great importance to the physician, are sometimes met with. These forms, which show considerable clinical variety, are collectively known as *pernicious attacks*. As their name implies, they are dangerous to the patient; but, fortunately, they are comparatively rare. They occur chiefly in very malarious localities and seasons; and among those who have already suffered from a few attacks but have not yet become habituated to the poison, especially among those who have been exposed to hardships and have not been adequately treated. As a rule, pernicious attacks are associated with very large numbers of parasites—not necessarily found in the peripheral blood, but present in the body as a whole, or in certain organs.

A remarkable fact about such paroxysms is that they are found almost entirely in connection with the æstivo-autumnal parasites, especially the tertian variety. As already mentioned, these parasites, as soon as they grow to any considerable size, tend to disappear from the peripheral circulation and to congregate in the spleen, liver, bone-marrow, brain, or digestive tract (this statement does not include the gametocytes of this species). Hence, if the total number of organisms is very large, we are apt to find, in addition to the ordinary symptoms of the paroxysm, certain grave symptoms referable to the organ or organs most attacked. Such cases are also known as *comitate* or *complicated attacks*.

Simple or Hyperpyrexial Pernicious Paroxysm.—This name should be reserved for cases in which the symptoms are referable simply to superintoxication without implication of any special organ. Death is threatened or occurs as the result of hyperpyrexia, accompanied by the usual symptoms.

Cerebral Pernicious Attacks.—These are referable to the accumulation of immense numbers of æstivo-autumnal parasites in the cerebral and meningeal capillaries. Sections often show the vessels crowded with mature sporocytes, leading to stasis and hyperæmia. The principal clinical forms produced are as follows. The *comatose* form; headache and stupor followed by coma; pupils contracted; respiration slow—occasionally Cheyne-Stokes breathing; sometimes spasms; reactions often entirely abolished. Death is frequent, and the cases are very apt to be mistaken for sunstroke. Fever is not necessarily high. Other forms are indicated by their names—*ataxic*, *tetanic*, and *delirious* forms. *Fits* are common in children during the paroxysm. *Bulbar paresis*, *hemiplegia*, *paraplegia*, and *amblyopia*, are all known to occur, but if death does not intervene, all are completely or nearly transient. Cerebral and retinal *punctiform hæmorrhages* are not uncommon. *Meningeal* and *choreal* types are known. In all a fatal result may occur as a result of secondary lesions, some days after the parasites have been reduced by quinine.

Gastro-intestinal type.—The capillaries of the digestive tract are often the seat of a parasitic stasis, leading to symptoms referable to this tract. The most important form is the *choleraic*, which closely simulates cholera. The stools, however, do not become entirely choleraic, though death may occur. *Dysenteric*, *diarrheal*, and *melanic* attacks are also known; but the observer must be on his guard against mere concurrent affections in such cases.

Bilious type.—In this there is polycholia of a hæmatogenous order, derived from excess of hæmoglobin thrown into the liquor sanguinis during the paroxysm. These cases are characterised by jaundice, dark stools and urine, vomiting, high fever, rapid blood-destruction, death under coma, or slow recovery.

Algid type.—Though numerous parasites and all the other symptoms of the paroxysm are present the fever may be almost entirely absent—and this not as a result of habitude. The pulse may be almost lost, and collapse follows. The pathogeny is not known.

Other types are the *sudorific* type, in which the sweating stage is followed by collapse; the *syncopal* type, in which fainting occurs; the *gastralgic* type, associated with sharp epigastric pain and vomiting; the *hæmorrhagic* type, with epistaxis, hæmoptysis, &c.; lastly, the *pneumonic* type, simulating pneumonia but not consisting of a concurrent pneumonic attack; there is painful cough and bloody sputum, with a moderately dull note over the lung.

Post-malarial fever.—This is a name given to a continued fever, which is not directly due to the parasites, but which sometimes sets in after a grave malarial paroxysm. It is most probably produced by secondary lesions caused by the organisms during the paroxysm. It is not amenable to quinine; and may last many days. It is remarkable that during its course the number of corpuscles may continue to fall, and even death may occur, though for many days the parasites may have disappeared as the result of previous cinchonisation. Needless to say, the observer must show reserve in giving this name to cases in which the organisms are not found at once.

5. *Procession of Paroxysms.*—We have confined our attention hitherto to the *single* paroxysm and its

modifications, because it constitutes, so to speak, the *pathological unit* of an acute malarial infection. The sequence of events consists of a series of these units disposed in a more or less regular order. The paroxysm tends to recur every one, two, or three days, according to the species of the pathogenic organism. But at the same time this type is apt to be modified by several circumstances which it is necessary now to examine.

Single Infections.—A single infection is one in which each paroxysm is due to the progeny of the parasites which caused the previous paroxysm. Thus in a *single quartan* infection, if a first generation of parasites caused fever on the first day of a month, the next paroxysm would be caused by their progeny on the fourth day of the month; the third paroxysm by the third generation on the seventh day; and so on—there being no paroxysms between these dates. Similarly in a *single tertian* infection (whether the parasites are the ordinary or the *æstivo-autumnal tertian* parasites) the paroxysms occur every other day. Lastly, in a *single quotidian* infection, one paroxysm occurs every day.

Double Infections.—Here we have two series of parasites of the same species sporulating at different times. Thus in a *double quartan* infection, while one series causes paroxysms on the first, fourth, and seventh of a month, another series may be causing paroxysms on the second, fifth, and eighth days, the third, sixth, and ninth days being fever-free. Or perhaps the second generation may sporulate on the third, sixth, and ninth days, the second, fifth, and eighth days now being fever-free. Similarly a *double tertian* shows paroxysms not only on the first, third, and fifth days, but also on the second, fourth, and sixth days; while a *double quotidian* may have one series of paroxysms every morning, and another every evening.

Lastly a *triple infection* is one in which there are three series of paroxysms due to the same species of parasite. Thus in a *triple quartan* the patient has one series of attacks on the first, fourth, and seventh days; a second series on the second, fifth, and eighth days; and a third on the third, sixth, and ninth days.

Hence it is apparent that a quotidian fever is not necessarily always caused by the quotidian parasite. It may also be due to a double tertian or a triple quartan infection. It is remarkable, however, that there is often a notable difference between quotidian fevers due to the different species, because, with the quartan and tertian parasites one series of paroxysms is *stronger* than another; so that the type is still visible on the temperature-chart by a higher fever on every other day with the tertian parasite, and on every third day with the quartan parasite.

Remittent, Subintrans, or Subcontinuous Fevers. Other circumstances which influence the fever curve are the normal modifications to which the paroxysm is subject. The most important of these is the prolongation of the paroxysm due (a) to infection by the *æstivo-autumnal tertian* parasites, or (b) to sporulation not being simultaneous, or (c) to want of habituation in the patient. In such cases the paroxysms are apt to run into each other; a second begins before the first has ceased; and we obtain what is called a malarial remittent fever.

This point should be carefully noted. A remittent fever is not fundamentally different from an intermittent fever; it is merely due to the coales-

cence of attacks, with absence of the usual intermission. It is always apt to occur during the first days of fever due to any species of parasite. It is, however, especially liable to occur in the *æstivo-autumnal tertian* infection, because of the ordinary length of the paroxysm in such cases; and also in the *æstivo-autumnal quotidian*, because of the short life-cycle of this parasite and its tendency to sporulate irregularly. Thus remittent fever is generally, though not always, associated with the *æstivo-autumnal* parasites.

Another source of variation in the chart is the *anticipation or retardation* of sporulation which sometimes occurs.

Lastly, in grave or complicated cases, post-malarial or other secondary fevers obscure the periodicity of the attacks. In all these cases, however, the observer should remember that the beginning of a fresh paroxysm is generally marked clinically by an access of fever, often accompanied by chills or rigors, and microscopically by the appearance of young parasites in the corpuscles.

6. *Rallies and Relapses.*—After a few weeks of fever, even without treatment, a *rally* usually occurs. The fever, perhaps at first remittent, becomes intermittent; then, in complex infections, first one and then another series of paroxysms cease, the chart being modified accordingly. Reparation of the blood takes place; the fever-producing forms of the parasite disappear; the temperature stands below normal; and the patient thinks himself recovered and resumes his avocations. This improvement may last for days, weeks, or months; but if treatment has not been continued, and especially if the climate is tropical, a relapse is almost sure to happen. All the old symptoms recur, and the parasites are found again. After this relapse has lasted some time, there is a second rally, followed perhaps by a second relapse; and rallies and relapses alternate, sometimes during years. On the other hand, permanent recovery, either spontaneous or the result of treatment, or death may intervene at any moment.

Examination of the blood generally shows that the fever-producing forms of the parasites are absent during the rallies and present during the relapses; but the gametocytes, especially of the *æstivo-autumnal* parasites (called *creascent*s) may be found also during the rallies. It has been suggested that the organisms enter upon some latent phase during the rallies; but the simplest theory (and one which is supported by a study of the parasites of birds) is that they only diminish so much in number as to become at once insufficient to cause fever and difficult to find in the small quantities of blood usually examined. We can readily understand how even a few scores of parasites may keep the infection alive for years without being numerous enough to produce any symptoms whatever.

The relapses are precipitated by exposure, fatigue, chills, indigestion, and intercurrent affections, by anything, in short, which tends to reduce the vitality of the host. Nothing is commoner in the tropics than to see bands of native workmen or soldiers attacked by epidemics of fever immediately after commencing some severe labour. Such cases are often only relapses among persons already infected. Owing to the same facts even intelligent persons often ascribe their fever to chills.

In malarious localities many apparent relapses may really be due to reinfection; and our present knowledge shows that, if *Anopheles* be present, a

patient may become reinfected even from himself. On the other hand, true relapses certainly occur in persons long removed from malarious areas. Such cases are found with all the species of parasites: the quartan is especially obstinate.

7. *Chronic Malaria*.—The condition just described is known as chronic malarial disease; and consists of a continued infection in which the parasites occasionally become numerous enough to produce fever, together with the development of certain important secondary symptoms. As the disease progresses, three series of phenomena manifest themselves: (*a*) the parasites tend to become less and less numerous; (*b*) their toxin produces less and less effect; and (*c*) the accumulated effect on the system of successive paroxysms becomes more and more marked—producing the secondary symptoms.

These consist principally of *anæmia*, *melanosis*, *siderosis*, enlargement of the spleen and liver, and perhaps a secondary fever. The *anæmia* is due partly to the blood-destruction which takes place in the paroxysm, and in part probably to the state of the organs. During the earlier paroxysms, each attack is followed by a sensible reduction of corpuscles; but this reduction tends to become less and less with each relapse; and finally a constant oligocythæmia, standing at 1,000,000 corpuscles per c.mm. or even less, is arrived at. Grave paroxysms precipitate this result. The oligocythæmia is associated with nucleated normoblasts and leucopenia, in which the large mononuclear cells are said to be relatively above the normal in number. True pernicious *anæmia* with megaloblasts is certainly found, especially among pregnant women and the aged (Marchiafava and Bignami). The *melanosis*, due to the constant deposition of black pigment in the organs, grows more intense as the infection advances, but tends to be eliminated as the invasion subsides. On the other hand, *siderosis* (deposition of yellow pigment) increases as the invasion subsides. The *spleen*, sensibly enlarged even after the first paroxysm, increases with each relapse, until it may reach almost to the crest of the ilium and beyond the umbilicus. The *liver* shows a similar enlargement, extending several inches below the costal margin. Both organs may be indurated, and may be tender on pressure, or may even be the seat of a dull aching. In cases of grave, and especially of tender, tumours, the writer has found in India a condition of *cachectic fever* of a continued type, oscillating within a few degrees above normal, not accompanied by parasites even in the splenic blood, and not amenable to quinine. He is inclined to attribute it to the state of the organs; to which Kelsch and Kiener refer their *fièvre symptomatique*, which is probably the same thing. Debility, emaciation, cardiac bruits, epistaxis, darkening of the skin, occasional icterus, diarrhoea, constipation, dyspepsia, and, later, œdema of the feet and face, and ascites, fill in the outline.

It is important to note, however, that in many cases, especially among well-to-do or habituated persons, secondary symptoms scarcely appear, chronic malaria finding expression only in occasional paroxysms occurring at long intervals. It also seems that enlargement of the liver and spleen depends upon local and racial conditions as well as upon malaria. Thus the writer has not found it in one or two severe and lasting endemics. Rogers gives observations tending to show that splenic tumour may depend on impurity of water-supply.

Daniels shows that while a very large percentage of negro and Indian children possess splenic tumour in British Guiana, the former recover from it first. It is probable that various conditions or complications, such as habitude, climate, poverty, food, diarrhoea, dysentery, and helminthiasis, modify the secondary symptoms in many ways.

8. *Malarial Cachexia*.—As the disease progresses further, the parasites disappear entirely in many cases, even the melanin being eliminated from the spleen. This is shown by examination of splenic blood during life; and Daniels (confirmed by the writer) shows that a considerable percentage of greatly enlarged spleens and livers found at autopsies contain no melanin at all. In such cases, however, the secondary symptoms—anæmia, splenic and hepatic tumours, &c.—are very apt to remain after the extinction of the invasion; and we obtain the final condition of malarial cachexia.

In early cachexias it is probable that the secondary or cachectic fever may be present; but later on, especially as the splenic tumour becomes indurated and then decreases, the temperature falls to sub-normal, and a state of extreme debility, with any or all of the symptoms noted above, remains. Death may occur from asthenia, or more commonly from complications, especially from pneumonia during the cold season, and diarrhoea and dysentery during rainy seasons. On the other hand, complete recovery may set in even at this stage, especially in children and well-fed and well-treated persons.

9. *Sequelæ*.—Owing to the length of the chronic malarial infection, it is always difficult to say whether a sequelæ is a resulting or an intercurrent affection. Paresis, paralysis, aphasia, ataxia, and chorea, sometimes follow grave paroxysms. The pathogeny of nervous sequelæ is traced chiefly to cerebral or cerebellar punctiform hæmorrhages. *Ulcerative enteritis*, *acute and chronic nephritis*, *albuminuria*, and *glycosuria* are fairly well established sequelæ both of parasitic and cachectic malaria. *Cirrhosis* of the liver is given by Kelsch but disputed by others. *Punctiform hæmorrhages* of the retina and *deafness* are sometimes found. *Rupture* of the *spleen* from slight injuries is far from uncommon. Most important sequelæ, if they can be called so, are *poverty* owing to the inability to work, and perhaps a proneness to *helminthiasis*. Generally speaking, malarial disease has no phlegmonous tendency. (See also p. 770.)

10. *Complications*.—The condition of things which has been called *typho-malarial fever* should be looked upon as being a mere concurrence of the two diseases. Typhoid fever like other disease (e.g. gonorrhoea) is apt to bring on relapses of malarial fever. A more important and very fatal complication is that of *pneumonia* in malarial cachectics. *Dysentery* and *diarrhoea* are almost as frequent and fatal associations in the tropics. The writer is of opinion that *ankylostomes*, *round-worms*, *whip-worms*, *amæbe*, and *cercomonads*, all tend to be more common in poor malarial cachectics. *Insolation*, *tropical hepatitis*, and *abscess* are often associated with all stages of the disease. The physician should remember (*a*) that intercurrent infections predispose to malarial relapses, and (*b*) that the reduced vitality due to chronic malaria seems to predispose to intercurrent infections.

DIAGNOSIS.—The physician may be required, not only to distinguish the disease at any stage from other affections, but to determine the species of

the parasite, the severity and progress of the invasion, or the presence of post-malarial and cachectic fevers.

During the first paroxysms a prompt and definite diagnosis cannot always be made on clinical grounds alone—at least in early cases. In many instances the first paroxysms have a subinfrant character; the fever is remittent and approaches the continued type; and the secondary symptoms have not yet developed. Hence, as it is bad treatment to delay the exhibition of quinine until the rhythmical quality of the fever declares itself, immediate examination of the blood is often demanded. In the majority of cases this clinches the diagnosis at once by revealing the presence (a) of the parasites, and (b) of pigmented leucocytes. In the first one or two paroxysms, however, both parasites and melaniferous leucocytes may be still too scarce to be easily detected. In such cases we are often guided by the leucopenia and large number of mononuclear cells after the crisis (Christophers and Stephens). The same condition may, however, occur in typhoid fever.

In *somewhat older infections* both parasites and pigment and the periodical nature of the fever become almost invariably manifest. To find the first with certainty, however, the physician must be a practised observer; he must be able to detect the small amœbule of the æstivo-autumnal parasites; he should search the blood when the temperature is rising; and may have to search it more than once. As regards the fever, although the classical curves may not be established, a sudden drop to below normal (e.g. to 97° F.) is very indicative of malarial fever, if powerful antipyretics have not been given.

Still later the occurrence of relapses and the appearance of splenic and hepatic tumours and of the dusky complexion are additional aids to diagnosis. In *old cases*, when the parasites are absent or too scanty to be found, we must rely upon the secondary symptoms and the character of the anæmia. Ankylostomiasis is very apt to be taken for malarial cachexia. In early cases of the former the ova of the worms are to be found; in those of the latter, splenic and hepatic tumours exist. Advanced cases of both, however, may often exhibit little difference, except perhaps in the deeper anæmia of ankylostomiasis.

The curative effect of quinine in malaria is always a valuable aid to diagnosis. Post-malarial and cachectic fevers are distinguished by their continued type, by the absence of fever-producing parasites, and by resistance to quinine. Examination of the splenic or hepatic blood is demanded in some cases.

DETECTION.—The microscope must have a one-twelfth oil-immersion lens, and a sub-stage condenser. Use the flat mirror. Do not place too near the window. Employ as much light as is consistent with good definition—pigment shows best in a bright light. To cleanse glasses in water will suffice. New cover-glasses must be soaked in acid and then washed. Rub the finger dry and clean before pricking. Prick the insensitive skin above the nail. The blood must come easily. Take up on the cover-glass a drop the size of the head of an ordinary pin. Wipe the slide. Drop the charged cover-glass upon it from the height of half an inch. Examine fields where the corpuscles lie fairly separate but are not crushed; for the larger parasites thicker fields will suffice. Do not waste time over bad fields or specimens. The student must make

himself familiar with vacuolated and crenated red corpuscles, dirt and flaws in the glass, blood-plates, &c., by studying his own blood. Vacuoles have a thick refractive margin, appear to alter in size with change of focus, and often quiver within the corpuscle—things never seen with amœbulæ. Ring-shaped and eye-shaped vacuoles are sometimes seen, but these are seldom quite circular like amœbulæ. If *only* small amœbulæ, or only those with crescents, are present, the case is æstivo-autumnal. If larger pigmented forms, still enclosed in corpuscles, are numerous, it is quartan or tertian. In this case, if the infected corpuscle is small, we have a quartan; if large, a tertian case. Crescents which have become spherical may be mistaken for large quartan and tertian organisms, but the former are not enclosed in corpuscles. Examine at the beginning of the paroxysm. A parasite will generally be found in one in ten fields; sometimes several occur in one field.

To *dissect mosquitoes*, kill with chloroform and examine fresh. Pass a needle through the thorax and hold down the insect in a drop of water placed on a glass slide. With another needle separate the last two tail-segments. Pull out the stomach, intestine, Malpighian tubes, and ovaries. Examine the stomach for zygotes, first with low and then with high power. They will be seen as small circles containing melanin when young; as large spheres later. For the salivary glands use fairly strong salt-solution and tease out the scales near the neck. The blasts will appear like snips of thread in the body-fluid or in the cells of the gland. Insects gorged with blood should be kept alive for a day or two until the stomach has emptied itself. They need water and bananas to be kept living for long.

Staining is not necessary for diagnosis, and cannot be discussed here. Almost any method suffices merely to colour the parasites, both in man and in the gnat; but in order to distinguish the nucleus the Romanowsky method should be employed, and the reader must study the monographs on malaria.

To examine *splenic* or *hepatic* tissues during life insert a rather large hypodermic needle (without the syringe), the patient holding his breath. Leave *in situ* for about 60 seconds, during which the needle fills with blood. Withdraw and blow out the blood and tissue cells upon a slide. Parasites and black and yellow pigments can easily be found. The writer has never observed any real inconvenience produced.

Since the life of the whole group or horde of organisms coincides exactly with the life of any one of the individuals constituting it, it will readily be understood that in a single infection by the quartan parasite sporulation occurs only every 72 hours, that is, every third day; in the tertian it occurs every other day; in the æstivo-autumnal every day or every other day according to the variety.

In the case of double and treble infections there are two or three distinct hordes of parasites of the same kind in the same host—distinct, because at a given moment they present different stages of growth. Thus, when one horde is sporulating, another is still growing, and will sporulate tomorrow or the next day according to the species. Similarly we often see *mixed infections*—that is, cases in which hordes of two or even three different kinds of parasites exist in the same host. In all these cases each horde continues to propagate inde-

pendently of any others which may be present along with it.

The parasites pass the greater part of their existence safely ensconced within the corpuscles and engaged simply in growing. Their only effect during this period is to consume and destroy the individual corpuscles in which they happen to lie. But when the moment comes for them to rupture the corpuscles and scatter their spores in the liquor sanguinis, other and more important phenomena assert themselves. Together with its spores, each parasite liberates a few black granules of melanin—the altered hæmoglobin which it contains. This is ultimately taken up by the phagocytes of the blood, and finally finds its way to the spleen and other organs, which in the course of time it renders melanotic. At the same moment, moreover, each parasite liberates a minute quantity of some toxic substance. If the whole horde of parasites sporulating at the moment be a large one, the total amount of toxin liberated must also be large; and if this be sufficiently large, it produces the fever and other symptoms which are characteristic of a typical attack of malarial fever. Hence it follows that the attacks of malarial fever coincide in time with the sporulation of each successive horde of parasites; and, since this occurs at regular intervals of one, two, or three days, according to the species of parasite concerned, the successive attacks of fever must show a similar rhythmical periodicity—which is, in fact, the distinctive peculiarity of malarial fever.

PROGNOSIS.—This is much better in temperate than in hot climates; and in those who take quinine well, who can afford good food and removal from malarious localities, and who belong to habituated races. Pernicious attacks are certainly much less common with the quartan and tertian parasites; on the other hand, these parasites often produce very obstinate infections in hot climates. Nearly all infections *can* be stamped out if taken in time. Recovery is often complete even from very severe cachexias. Pernicious attacks are very fatal—especially the cerebral and choleraic forms, particularly when occurring after considerable anæmia has been already established, or in old people. Pneumonia, chronic dysentery, and diarrhoea are grave complications. Amyloid degeneration necessitates a bad prognosis. As a rule the prognosis is good in malarial disease if the patient can and will follow the directions of his medical adviser.

TREATMENT. 1. Preventive.—*Personal.*—In all malarious localities mosquito-curtains should be scrupulously used during sleep. They should be entirely free from the smallest holes, rents, or apertures; should be carefully tucked under the mattress or bedding; and should be entered with precautions to prevent the simultaneous entry of gnats. A punkah over the curtains adds to the safety and comfort of the sleeper; and punkahs should be used in the days and evenings as much as possible. *Culicifuges* are not to be trusted.

Quinine is a very good prophylactic. The writer prefers 5 to 10 grains daily before breakfast. Others recommend 15 grains or so twice a week. It is certain that infection can be largely postponed, if not entirely prevented, even in the most malarious districts, by persons who employ such measures with care and common-sense.

Domestic.—Punkahs, fixed wire-gauze screens to the windows, whitewashed walls, and removal of

all stagnant water from tubs, flower-pots, and depressions in the ground are called for.

Barracks, gaols, hospitals, and rest-houses should always be carefully attended to in these respects. Patients suffering from either acute or chronic malaria should be invariably protected by nets.

Segregation.—Europeans generally contract the disease through the agency of *Anopheles* from natives—especially from native children—living in their vicinity. In all malarious tropical towns the Europeans should live in a separate quarter. The houses should be large airy structures, the rooms being whitewashed or painted white, and provided with a white ceiling. Surrounding bush should be cleared as far as possible—though a few large trees may be left.

Municipal measures.—In all towns possessing sanitary agencies, the whole area should, if possible, be gradually drained and levelled so as to remove all pools where *Anopheles* may breed. Agents should also be employed to destroy larvæ by oil or tar, or by overturning vessels of stagnant water. In the writer's opinion these measures will be likely to protect a larger number of people at less cost than measures of personal or domestic hygiene alone can do. Koch recommends treating a whole population with quinine; this may be practicable in certain isolated communities.

The best rule is to adopt as many measures as are possible under local conditions.

Exemption.—A certain degree of exemption is certainly often acquired by those who have passed through a long malarial infection. Thus a large percentage of native children suffer from the disease in all its stages; but as they grow older they throw it off; and, though they occasionally suffer later from fever, they do not suffer much. Hence, adult natives often seem to escape where Europeans contract grave infections. No means of conferring protective properties is known.

2. Curative.—Quinine is a specific against the propagation of the parasites within the blood; but it must be employed in a skilful manner. The object is not to reduce a given attack of fever, but to rid the system of the parasites entirely. Immediately after a definite diagnosis is obtained, the drug must be given *promptly* and in *sufficient doses*, and must be *continued for months*. The writer considers it a grave mistake to withhold it until the temperature falls below normal; though, perhaps, *excessive* doses should not be employed when there is high fever. The most effective time for administration is about an hour before the commencement of an expected paroxysm; but in the early remittent stages quinine should be given thrice daily. As a rule, the daily amount for an adult need scarcely *exceed* 30 grains, distributed according to the physician's discretion. The amount of 'singing in the ears' is a good test of the degree to which the system has been saturated. A useful rule is just to maintain a considerable degree of singing in the ears while the parasites or pigmented leucocytes are sufficiently numerous to be detected, and for a week afterwards. In a hot climate the parasites appear to be much more resistant to quinine than in a temperate one. After the attack or relapse has passed off for a week, the dose may be reduced to 10 grains daily before breakfast, and 5 grains again in the evening—to be continued for another two weeks. Then, gradually, further reductions may be made. Manson recommends 15 grains in

three doses once a week. The susceptibility of the patient must be a guide. The drug must not be entirely abandoned for at least three months after an attack.

The writer always recommends quinine to be given in acid solution just before a meal, the first mouthful of food being swallowed just after the medicine. This removes the taste at once, and mitigates the irritant effect on the stomach; while singing in the ears often announces absorption within half an hour. Pills and capsules are apt to become insoluble in damp tropical climates. Rectal or hypodermic administration is often necessary: in the former case, up to 20 grains or more thrice daily; in the latter, up to 10 grains thrice daily. The physician should always keep special tabloids of quinine, and a good syringe for hypodermic use (see HYPODERMIC MEDICATION). If he possesses only the sulphate, this should be dissolved by adding half its weight of tartaric acid with the requisite amount of boiled water. The syringe and needle should also be boiled; and the injection made into muscle.

In *chronic malaria* it is not necessary to press quinine unless there is evidence to show that the parasites are still present. Small doses suffice at this stage; but on the other hand, close attention must be given to the secondary symptoms. Arsenic, iron, and sodium sulphate and bicarbonate are undoubtedly beneficial. Starved cachectics require careful feeding. At all stages removal to a temperate climate, sea-voyages, or courses of medicinal waters are to be recommended.

Subsidiary symptomatic treatment is not to be neglected; but details must be left to the physician. Purgatives and also opium are often most useful. Methylene blue has been rather discredited. Warburg's tincture is valuable (dose about one table-spoonful). Antifebrin and phenacetin are much abused, and the writer even thinks that they may be harmful if given before the crisis, or too frequently. In hyperpyrexia tepid baths are better. A full knowledge of the pathology is the first essential of treatment; and the physician is not justified in neglecting the logical use of quinine for popular nostrums. In malarious localities the patient must invariably sleep in well-arranged mosquito-curtains, to avoid infecting others and re-infecting himself. Quinine must be well pushed in pernicious attacks. Entozoa should be expelled.

MALFORMATIONS (*male*, amiss; and *formo*, I fashion).—SYNON.: Fr. *Malformations*; Ger. *Missbildungen*. See MONSTROSITIES.

MALIGNANT DISEASES.—This term is applied, first, to tumours which, without any natural limitation, gradually involve the surrounding tissues, reproduce themselves in distant parts, and, if unremoved, inevitably lead to the destruction of life; and, secondly, to certain varieties of fevers and other acute affections, such as typhoid fever, scarlet fever, small-pox, and cholera, which present peculiarly grave and aggravated symptoms, and generally end in death.

MALIGNANT PUSTULE.—See PUSTULE, MALIGNANT.

MALINGERING.—See FEIGNED DISEASES.

MALLEIN.—See GLANDERS.

MALTA.—A warm, moist, and variable winter climate. See CLIMATE, Treatment of Disease by.

MALTA FEVER.—SYNON.: *Febris undulans*; Mediterranean Fever; Gastric Remittent, and Bilious Remittent Fever; Rock-Fever (Gibraltar); Neapolitan Fever, &c.

DEFINITION.—An endemic disease of long duration, characterised by fever, enlarged spleen, profuse perspiration, constipation; by almost invariable relapses: accompanied by pains of a rheumatic or neuralgic character, and sometimes swelling of joints or orchitis; and characterised in fatal cases by enlargement and softening of the spleen, no swelling or ulceration of Peyer's patches, and the constant occurrence in various organs of a species of micrococcus.

GEOGRAPHICAL DISTRIBUTION.—Formerly this fever was believed to be confined to the shores and islands of the Mediterranean, where it is widely distributed; recent investigations tend to show that it occurs in other places—India, Brazil, Cuba, Puerto Rico, Hong-Kong, Manila, and even in England.

ÆTIOLOGY.—Malta fever is probably due to the introduction into the system of a specific micro-organism (*Micrococcus melitensis*). This assertion is based upon the following facts: (1) This micrococcus is found in the organs of every fatal case. (2) This bacterium can be readily cultivated outside the body. (3) Inoculations of pure cultivations into monkeys have caused fever and death. (4) From the organs of these monkeys the identical micrococcus has been abundantly obtained. (5) Inoculations of cultures have been followed by the disease in man. (6) The serum of the subjects of Malta fever, in high degrees of dilution, causes agglutination and sedimentation of cultures of *Micrococcus melitensis*. As to how, under natural conditions, this micrococcus gains entrance to the organism nothing definite is known. There is no evidence that Malta fever is communicated directly from individual to individual. One attack of Malta fever probably confers immunity against a second.

Age and Sex.—This disease chiefly affects young persons between the ages of ten and thirty; less frequently under ten, and from thirty to fifty; and very rarely above fifty. It does not seem to occur among infants, or if it does it is not recognised. Sex has little influence, but the complaint is more common among men than women.

Station in life.—Malta fever attacks the well-to-do classes, living in large well-ventilated houses, probably in as large a proportion as it does the poor in their more crowded dwellings.

Months and Seasons.—The summer is the season of the greatest prevalence of the disease, and, in the Mediterranean at all events, most cases occur in the month of July. A marked diminution takes place in autumn, and it is rare in the winter and spring months.

INCUBATION.—It is impossible to say definitely how long the period of incubation is, but the writer would put it approximately at ten days.

CLINICAL DESCRIPTION.—*Early Symptoms.* For the first week or ten days sleeplessness and headache are complained of, which may be mild or severe; the appetite is absent; there is nausea, sometimes vomiting, and a feeling of weight and tenderness in the epigastric region; constipation is

the rule, diarrhœa the exception. The spleen and liver are enlarged, and both may be tender on pressure. Tympanites is uncommon, but may occur, as also may gurgling in the iliac fossa. During this time almost invariably a slight cough with scanty expectoration is developed, and on examination the breathing at the bases is found to be unsatisfactory, harsh, and creaking in character, with now and then a moist crepitation. There is no eruption, but the patient suffers from a most profuse perspiration, and a more or less abundant crop of sudamina is developed. There may be a little delirium at night during this time, but this is rare, and is so slight as scarcely to call for remark. Unless there be headache or severe pain in the lumbar region, the patient for the first week or two usually professes that he suffers very little; at the end of this period the headache and acute symptoms usually disappear, and the long and monotonous period of the fever begins, a period which seems interminable alike to medical attendant and patient. The patient's aspect is natural but listless; his tongue is clean; he has a wish for solid food, which must often be denied; and his bowels require the stimulus of an aperient or enema for evacuation.

Later symptoms.—The profuse perspiration still continues, and day after day the patient becomes weaker and loses weight, until he has scarcely power to stagger a few yards. During this period the temperature often ranges high. The patient sleeps moderately well, has no delirium or restlessness, is uncomplaining, and takes without any ill effect a large supply of fluid food and stimulants. The only variation in his condition is afforded by a rheumatic affection of the joints; one day the knee is found red, swollen, and intensely painful on being touched, a few days afterwards a wrist or ankle may be attacked. Sometimes almost all the large joints in the body are affected in this way, or there may be intercostal neuralgia, sciatica, or an inflamed and swollen testicle. Thus many weeks may pass, but at last the temperature comes down to the normal, and the patient enters on a long and tedious convalescence.

Temperature.—The chief characteristic in regard to the temperature-curve in this fever is its irregularity. The type varies from the continued to the intermittent: one case is almost continuous throughout, another almost intermittent; some cases begin with a markedly intermittent type, and pass into the continued, while others begin as continued and pass into the intermittent. Some severe cases show a long irregular elevation of temperature, only reaching normal limits about the ninetieth day. The temperature-curve, as a rule, rises high, reaching 104°, 105°, and even 106° F.

DURATION.—Patients with Malta fever show an average stay in hospital of nearly ninety days. The length of the fever may vary from fifteen days to as many weeks or more.

DIAGNOSIS.—Apart from their respective serum-reactions, a severe rapidly fatal case of Malta fever cannot be distinguished from a similar case of typhoid except by *post-mortem* examination, when the absence or presence of a specific anatomical lesion in the small intestine at once separates the two kinds. If, as many hold, these fevers are caused by the entrance into the body of specific micro-organisms, then it is evident that the most rational and scientific method of classifying them would be by the identification of the parasite peculiar to each. In all cases

of Malta fever there is found a minute round or oval bacterium—the specific micrococcus; whereas in typhoid there is found a much larger rod-shaped micro-organism—the typhoid-bacillus. Principally through the labours of Professor Wright, a valuable aid in the diagnosis of Malta fever has been discovered in the agglutinating and sedimenting power of the serum of patients suffering, or who have lately suffered, from the disease on cultures of *Micrococcus melitensis* (see SERUM-REACTIONS). In the case of this bacterium the specific reaction is obtainable at an earlier stage (second or third day) of the disease, and with much higher dilutions (1 : 100 or more) than is the case with the corresponding test for typhoid fever. The specific property of the serum persists for many months—perhaps years. Ordinary cases of Malta fever can be distinguished from typhoid by their long duration, the tendency to constipation, the absence of a specific eruption, and the much smaller rate of mortality, which does not exceed 2 per cent.

TREATMENT.—This is a specific fever, and no drug at present known has any power of modifying its course. The sulphate and salicylate of quinine, Warburg's tincture, eucalyptus, calomel, salicylic acid or the salicylates, carbolic acid, and other drugs have been tried again and again for this purpose, but without any good result. Medicinal treatment must therefore be directed to mitigate severe symptoms. At the beginning of the fever phenazone is often found useful to combat severe headache and sleeplessness. For the constipation a mild aperient or simple enema will very often prove necessary. For the neuralgic and articular pains, hypodermic injection of morphine, and the liniments of aconite, opium, and belladonna will be prescribed. Treatment must therefore be principally directed to keeping up the patient's strength by judicious dieting, and, when required, by stimulants, and by attention to ordinary hygienic principles. Removal of the patient from the affected area does not cut short the course of the fever; but, as in many other diseases, complete restoration to health will certainly be hastened by change of climate.

MAMMARY GLAND, Diseases of.—See BREAST, Diseases of.

MANIA (*μανία*, fury, madness).—SYNON.: Fr. *Manie Suraigue*; *Délire Aiguë*; *Fureur*; Ger. *Tobsucht*; *Wuth*.

Under the term 'mania' very distinct disorders or degrees of disorder have been described, which we shall speak of as *Acute Delirious Mania*; *Acute Mania*; and *Mania*.

I. Acute Delirious Mania.—An outburst of delirious mania may take place after very few and very short premonitory symptoms. Quite suddenly, after a few days or even hours, the patient will display the most violent excitement, which may as suddenly subside, or run a well-marked course of a few weeks; and if it does not terminate fatally will gradually decline, recovery usually taking place. Such an attack may have its origin in some sudden mental shock, as the death of a friend, a violent quarrel, a disappointment or suddenly announced misfortune; or it may arise in the course or decline of an acute disease, as pneumonia or measles.

It may also come on during rheumatism, or after great fatigue, an epileptic seizure, or childbirth. A theory lately propounded that this disorder is due to autotox poisoning is not at present supported by any evidence.

We cannot tell at first whether the attack will be transient or prolonged. We may try to cut it short by a brisk purgative, and by such medicines as chloral hydrate and bromide of potassium, a subcutaneous injection of hydrobromate of hyosine, or a full dose of paraldehyde; and these not infrequently answer the purpose. Sleep is procured, and perfect recovery may take place in a few days. There are patients whose organisation is so unstable that it is thrown off its balance by a cause perhaps trifling, but which produces a tremendous nerve-discharge and complete disturbance of the whole mental functions. But so transient may this be, that one sleep restores the normal equilibrium, and the patient is cured. This condition in females is often called hysterical—*hysterical mania*. There is no special connection between it and the uterine functions, and it is better to retain the name 'hysterical mania' for a variety to which it may be more appropriately given.

The delirium, however, does not always terminate quickly. If sleep becomes less and less, the mind more and more confused, and quiet and lucid intervals rarer, we may be sure that the attack will be serious and prolonged, and that careful and efficient nursing for some time will be necessary. Where a quiet and airy room can be provided, and a patient's means are sufficient to allow him an adequate staff of attendants, an asylum is not indispensable. He will not require to take exercise in a garden; he will not be dangerous, as some are, to himself or others, though he may be violent and excited. He may be noisy, however, and so not able to remain unless the house is detached. The room should be lofty and cool, the windows protected and darkened; all furniture must be removed, and the bed made on mattresses placed on the floor, for he will not lie on a bedstead, and attempts to keep him there will end in bruises or more serious injury. Clothes will be torn off; but if the weather is very hot, as is so often the case during these attacks, this will be of little consequence. If it is cold, a strong suit laced up the back may be put on, and underneath it the requisite body-clothes; or a blanket may be placed round the patient, and fastened up the back.

These patients are in incessant motion, singing, shouting, and talking in a string of incoherent utterances, often repeating the same sentence again and again, or a snatch of a song or text, or a rhyme of their own composition. As a rule they are not violent, and do not attack those about them, though they may resist that which is done for them. They may be hilarious and full of glee and mischief, which is a good sign; or terror-stricken, with visions of horrible objects, which is unfavourable. They are wet and dirty; and the urine will be high-coloured and often retained for a long period. We shall derive valuable information if we are able to take the temperature; but often that is a difficult task. A high temperature is a bad sign; and so is a rapid pulse if it continues persistently when a patient has not been using violent exertion for some time. The tongue will often become thickly coated, dry, and brown. If it does not, but remains moist and comparatively clean, this is of good omen.

PROGNOSIS.—The prognosis in these cases is upon the whole favourable. The terminations are almost always either recovery or death. The patients are mostly young persons, who recover unless weakened by previous attacks, other disease, or childbirth. Many of the fatal cases, in the writer's experience, have been complicated by tuberculosis.

TREATMENT.—Sleep in the attacks now under consideration is generally absent, sometimes for many days. Women can last longer without sleep than men, and die much less frequently in acute delirium. If sleep does not come the patient dies, and our great effort must be to promote sleep by various methods. The first question will be whether we are to give drugs to accomplish this; and, if so, what drugs. Opium must not be given; it will not procure sleep, whether given by the mouth or subcutaneously. It may produce a slight narcotism for half an hour or so, and, if we increase the dose, will cause narcotic poisoning and death; but in the height of the attack it will not procure sleep. Chloral hydrate we may try in combination with bromide of potassium, giving half-drachm doses of each, and watching the effect. In most cases sleep of longer or shorter duration will be caused by these drugs; and although it may be short, it may be sufficient to save the patient's life, and enable him to battle successfully with the disorder. In the writer's experience many more of these acutely delirious patients died before the introduction of chloral hydrate than since. Yet it must not be given in enormous or repeated doses, and a considerable interval should elapse between them. It may be administered easily in stout or ale, and often in wine. We may also give paraldehyde, or that powerful but somewhat dangerous drug, hyosine. Such drugs as these are not to be administered frequently, or at regular intervals. We wish to procure sleep enough to prevent the patient from dying by exhaustion; but in this very acute form no medicine is likely to produce more than a short sleep, and is more likely to do this if not given too frequently, and less likely to produce bad effects. Macleod has recently advocated the administration of large doses of the bromides—two drachms every two hours during the day till an ounce is given, and on the second day a similar amount. This produces a deep sleep, lasting some days, from which the patient must be roused and fed at regular intervals.

Next to sleep the most important matter is food. To enable the sufferer to withstand the exhaustion, which is the cause of death when a case ends fatally, he must be fed frequently and liberally, and, if necessary, by force (*see* FORCIBLE FEEDING). These patients rarely refuse food, but require careful coaxing and feeding; and a skilful attendant will give something every two or three hours—minced meat and vegetables, or bread and milk, beef-tea, eggs, and the like. Brandy often produces great excitement at the onset and height of an attack, and stout or ale is more suitable and more likely to bring about sleep. We may give also plenty of lemonade, barley-water, and such drinks, if there be great heat and thirst.

Although this unconscious or semi-conscious delirium may continue for many days, yet in almost every case the violence and excitement are paroxysmal, with intervals of comparative calm, even if there be no sleep. Judicious attendants will avail themselves of these quiet intervals to administer

food, and keep the patient in the recumbent posture, thus ensuring rest, instead of letting him be continually on his legs wandering about the room, and so exhausting his strength. And when held down quietly, with cold cloths applied to the head, or his face fanned by the nurse, he is not unlikely to drop off to sleep. Cold to the head may be applied, because it is soothing and grateful to the sufferer, though it is a question whether the circulation in the brain is most affected thereby.

The bowels may be kept open by a dose of calomel administered in the food, or by half-a-grain of resin of podophyllum. Active purgation is inadmissible except at the very outset, and enemata cannot easily be given in the violent stages. It used to be the fashion to apply blisters to the nape of the neck or calves. This is most inadvisable, for such parts may become very sore, owing to the restlessness of the patient, and thus deprive him of sleep. Neither is it necessary to cut all the hair off, which in the case of women may be a very grievous matter. If very long it may be shortened without being cut close to the head.

II. Acute Mania.—Quite different from the unconscious raving of maniacal delirium is the conscious but violent excitement to which we give the name of *acute mania*. The former is a disorder dangerous to life, running a rapid course to death or amendment in a week or two. The latter may go on for weeks or months with little danger to life, but with excitement so troublesome that the sufferers require the restraint and discipline of an asylum. Though most insane, full of delusions and outrageous habits of every kind, they know what they are about, and are all the more mischievous in consequence. They can take every advantage of an opportunity, and know how to exasperate those about them. They generally eat well, and sleep indifferently, but sufficiently to support life; and their bodily health often remains wonderfully good, considering what they go through. They will destroy clothes, windows, bedding, and deny or justify all they have done. The termination is not usually fatal, unless the health gives way through some other disease. The patients generally recover gradually, or sink into chronic mania or dementia.

PROGNOSIS.—The prognosis in cases of acute mania will depend upon circumstances. (1) The number and duration of the attacks are important. In a first attack the prognosis is favourable. If recent, we may have hopes, even if there have been preceding attacks of a like character. (2) If the patient is not of advanced age or of broken health, the prognosis is favourable. (3) If the mania consists of violent, turbulent conduct, rather than of fixed delusions, as is frequently the case, there is more hope. If the patient hears voices, the prognosis is bad. If there are delusions which impel him to refuse food, and he does so persistently and violently, it may be difficult to give sufficient nourishment, and he may sink from exhaustion, or become a chronic maniac.

TREATMENT.—Patients suffering from this form of mania do not require, like the last, to be kept in one room; on the contrary, they should take plenty of exercise in the open air. This will promote sleep more than drugs, though we may give an occasional dose of chloral hydrate, or bromide of potassium, or paraldehyde. Such medicines, however, should be given only to procure sleep, not to

allay excitement; we may also try sulphonal or hyosine. In many cases, however, sleep procured by drugs appears to prolong the attack, and, where there is no danger to life, it is better to omit them, and to let natural sleep come after the fatigue of exercise. Plenty of food is required, for the waste is great.

Patients of this kind are not to be cured or even kept without discipline and moral treatment; and great tact, firmness, and patience are required for their management. They may be very dangerous and spiteful, will know how to provoke attendants, and how to take them unawares if off their guard. Moral treatment will be far more efficacious than drugs, but it can only be carried out in an asylum. Patients in this condition, if kept in private houses, must be rendered quiet by drugs; but there is great fear lest by this method the disease, instead of being cured, may be converted into a chronic and incurable mania.

III. Mania.—A great variety of cases are grouped under this name, arising from various causes, but alike in the fact that they are marked by excitement rather than depression, by exaltation or wrath, but not by gloom. Excitement and noisy and irrational conduct characterise some, but most patients present delusions coinciding with their temper and bodily condition when in health. Almost always this form of insanity is marked by delusions, if it lasts long enough; but sometimes a short burst of excitement—a transitory mania—may pass away without the stage of delusion being reached, or there may be throughout outrageous conduct or extravagance without delusion.

The diagnosis of an ordinary case of mania is not difficult. The prognosis must depend on the cause; the age of the patient; the character of the delusions, if there be any; the occurrence or non-occurrence of previous attacks, and their history. Attacks of mania are frequently recurrent, and may be repeated again and again through a long life; recovery may take place on each occasion, or the disorder may at last turn into chronic mania or dementia. The period of excitement in many cases is followed by one of depression, and these may alternate with great regularity for twenty or thirty years; and even when the patient is sunk into hopeless dementia the period of excitement may occur as regularly as before the mental powers had given way.

TREATMENT.—Of the treatment of these cases a great deal cannot be said. The majority will require the care and vigilance to be found in an asylum, at any rate during the excited stage. The intervening or rational period will often be prolonged advantageously by removal from the asylum; and when this is the case there will be frequently found less reluctance to return to it when the necessity arises, and instances are not uncommon of patients even themselves seeking its shelter.

G. F. BLANDFORD.

MANIPULATION (*manus*, the hand).—The investigation and the treating of disease by the use of the hands. See PHYSICAL EXAMINATION; FRIC-TION; MASSAGE; and SHAMPOOING.

MANITOU SPRINGS, in Colorado, is famous for its mineral springs and as a high-altitude station, being situate 6,370 feet above the sea-level, in a sheltered valley of the Rocky Mountains at the foot of Pike's Peak. The climate is that of Colorado

Springs, six miles distant (*see* COLORADO SPRINGS), and the mineral springs consist of: (1) alkaline and saline, useful in affections of the kidney and liver; and (2) chalybeate alkali, of repute in uterine disease. The climate has been found valuable in the treatment of chronic phthisis. The neighbourhood of the great tracts of Manitou and Estes Parks, 1,000 to 1,200 feet higher than Manitou Springs, being available for camping-out, is an additional attraction.

MARASMUS (*μαρῖνω*, I grow lean).—A synonym for general wasting. *See* ATROPHY, GENERAL.

MARIENBAD, in Bohemia.—Alkaline sulphated waters and mud-baths. *See* MINERAL WATERS.

MARSH FEVER. - *See* MALARIAL DISEASE.

MASSAGE.—*SYNON.*: Medical Rubbing; Mechanotherapy; *Fr. Massage*; *Ger. Massiren*.

DEFINITION.—A series of mechanical movements, best executed by the hands of the operator, affecting not only the skin, but also the deeper structures of the body.

MODES OF ACTION.—Massage acts in the following ways: (*a*) it quickens the flow of the fluids (blood, lymph, chyle, and others); (*b*) it increases secretion and excretion; (*c*) it excites muscular action.

METHODS.—The movements in massage are of several kinds: (1) Stroking, or *effleurage*; (2) Pressure, or *pétrissage*; (3) Percussion, or *tapotement*; (4) Vibrations; (5) Passive movements; (6) Active or Swedish movements; (7) Medical gymnastics.

Stroking is performed by lightly drawing the hand in one direction over the surface of the part: on the head from the vertex, and on the spine from the neck, downwards; on the limbs, from the extremities towards the trunk. When *friction* is employed, greater pressure is made, and the hand is moved to and fro.

Pressure (squeezing, kneading, rolling, &c.). The pressure and relaxation should be alternate and rhythmical, simulating natural muscular action. During the pressure the veins, capillaries, lymphatic ducts, and lymph-spaces are emptied; and the valves in the vessels preventing the return of the expelled fluids, room is made for a fresh supply.

Percussion (tapping, beating, pounding, and others) causes muscular contraction.

Vibrations act in a similar manner.

Passive movements.—All the normal movements of the joints are fully executed by the operator, the will of the patient being in abeyance. The synovia is increased, if scanty—absorbed, if in excess; deposits around the joints are removed, and nutrition is promoted.

Active or Swedish movements are performed with the combined help of the patient and operator. The will of the patient is concentrated on the muscles under treatment. The patient is directed to cause a muscle to act, and the operator resists the movement, employing slightly less force. When the muscle has fully contracted, the operator employs more force, while the patient, diminishing but not ceasing his resistance, allows the part to be brought back to its original position. This is repeated a suitable number of times, but never so as to cause muscular exhaustion.

Medical gymnastics have for their object the

bringing into action those muscles which are seldom employed, or which, for some special reason, require strengthening.

USES.—The maladies, both medical and surgical, for which these therapeutic agents have been employed with success are very numerous. It must suffice to mention the following: Muscular weakness and wasting; infantile paralysis; Bell's palsy; lead-palsy; neurasthenia; neuralgia; sciatica; peripheral neuritis; anæsthesia; hyperæsthesia; chorea; hysteria; occupation-palsies; some forms of arthritic disease, as rheumatoid arthritis and chronic rheumatism; and the morphine-habit.

JOHN FLETCHER LITTLE.

MASTALGIA

MASTODYNIA

(*μαστός*, the breast; and *ἄλγος*, or *ὀδὴν*, pain).—Pain in the mammary gland. *See* BREAST, Diseases of.

MASTICATION, Disorders of.—Mastication is liable to be disordered from various causes.

1. *Muscular Paralysis*.—Imperfect performance of mastication is frequently the result of cerebral lesions, such as hæmorrhage or tumours. Dependent on the seat and extent of these will be the extent of the paralysis, which may vary from an impaired movement of one cheek, thus permitting the food to collect between it and the gum, to almost an absolute inability to move the lower jaw from side to side, or to close the mouth.

There are several special forms of paralysis in which the movements of mastication are affected, either alone or in common with other muscles of the body.

(*a*) *Labio-glossolaryngeal paralysis* is especially characterised by the impairment of mastication and deglutition, which progresses from a mere escape of saliva, due to paralysis of the orbicularis oris, to complete inability to perform either act. Of the masticatory muscles, it is those of the tongue and lips which are mainly affected. As the disease progresses to its invariably fatal end, the palsy increases in completeness.

(*b*) The loss of power in the muscles of mastication associated with *diphtheria* is far less frequent than paralysis of deglutition, and is usually limited to some weakness of the tongue, and less often of the lips and cheeks.

2. *Muscular Spasm*.—Trismus, or tonic spasm of the muscles of mastication supplied by the motor branch of the fifth nerve, is rarely unilateral. The jaws are usually completely locked, and incapable of separation, thus rendering mastication impossible. The trismus may be a part of a general condition of tetanus, or may be the sole indication of spasm; and in the latter case is usually reflex in origin, being determined by such causes as dental irritation, or facial neuralgia, or, more rarely, by distant wounds or intestinal worms.

Irregular clonic spasms of the muscles of the jaws, such as are frequently seen in chorea and hysteria, and are evidenced by chattering and grinding of the teeth, will offer some difficulty to the proper performance of mastication.

Spasm, whether tonic or clonic, when limited to the facial muscles supplied by the seventh pair, will interfere but slightly with mastication. By preventing the action of the lips and cheeks, the food will not be so easily kept between the teeth, and the saliva will dribble from the unclosed mouth.

3. *Affections of the Temporo-maxillary Articulation*.—Chronic rheumatoid arthritis may lead to such serious disorganisation of the joint as to impair its movements, ankylosis occasionally occurring.

4. *Morbid Conditions of the Mouth*.—Inflammation of the mouth or tongue, and disorders or absence of the teeth, render mastication difficult. Enlargements of the salivary or lymphatic glands, tumours of the thyroid body, epulis, and new-growths of the tongue, as well as abnormal apertures in the palate, floor of the mouth, or cheeks, caused by ulceration or noma, may interfere with mastication.

EFFECTS.—Portions of food imperfectly masticated may produce suffocation, by blocking up the entrance of the glottis, or lodging in the gullet. Imperfectly masticated food is a well-recognised cause of dyspepsia.

TREATMENT.—The treatment of disorders of mastication naturally consists in the removal of their cause, when possible. The reader is referred to the articles in which the several conditions are fully discussed.

W. H. ALLCHIN.

MASTURBATION (*manus*, the hand; and *stupro*, I ravish).—SYNON.: Fr. *Masturbation*; Ger. *Selbstbefleckung*.

DEFINITION.—The excitement of the sexual organs by unnatural means.

ETIOLOGY.—Masturbation is practised under a variety of circumstances. First, in infants and young children, local irritation situated beneath the prepuce in males, or within the vulva in females, leads to manipulation of the parts, and to consequent pleasurable excitement, which is constantly renewed, with an entire unconsciousness of the meaning of the practice.

The second class includes individuals who have reached or are near the age of puberty, and have either accidentally learned, or been taught, this pernicious habit. *Balanitis* is a frequent exciting cause. *Pruritus vulvæ*, due to diabetes mellitus or other causes, may lead to it in the female.

A third class of cases may be mentioned, in which the practice has a central origin, in certain forms of brain-disease, or cerebral deficiency, as is seen in some forms of insanity and in idiocy.

EFFECTS AND SYMPTOMS.—There is no doubt that the practice of masturbation leads to the most serious constitutional effects. These effects are more especially manifested in the nervous system. The mental faculties become more or less affected; and often great despondency, loss of memory, irritability, prostration of strength, headache, and neuralgic pains ensue. The functions of the heart are disturbed. Digestion is disordered. There is general loss of health and strength; and chronic hypochondriasis is set up. In certain cases the urinary organs are affected; and the writer has observed in several instances the constant presence of albumen in the urine, possibly the result of some reflex action on the nerves and vessels of the kidney. The effects on the male genital organs themselves are marked. There is extreme irritability of the neck of the bladder and adjoining parts, accompanied by discharge of mucus and of prostatic secretion, often mistaken for semen. At the same time seminal emissions are prone to occur on the least sexual excitement, either by day or during sleep; and in extreme cases there is impotence.

DIAGNOSIS.—When carefully concealed, the

practice of masturbation is difficult to discover. When, however, the symptoms just described are present, in the absence of any cause to account for them the practitioner may entertain a reasonable suspicion of the existence of this habit, although it may be difficult in many cases to carry his impression beyond the suspicion.

TREATMENT.—In the first class of cases above mentioned—that is, in young children, in whom some local irritation exists—the source of this irritation must be found and removed. Sometimes it may be an elongated prepuce, with irritating matter beneath it; in such cases circumcision may be required. In females cleanliness and simple lotions may suffice; or irritation, caused by the wandering of thread-worms, or the passage of diabetic urine, may require to be treated. In these cases attention to the general health, to the state of the digestion, to the urinary secretion, and to the bowels, should not be neglected. Diabetes mellitus must be treated if present. Extreme watchfulness by the nurse is necessary, and at night it may be even necessary to secure the hands by muffling or tying them behind the back.

In young adults the moral sense must be acted upon. It has been suggested, by way of prevention, that judicious and kind advice may with advantage be given before even a knowledge of the habit is acquired; while too much vigilance cannot be exercised by those who direct and assist in the management of schools.

In the actual treatment of the effects established by masturbation, it is of the highest importance to improve the health, both mentally and bodily. Early rising, healthful exercise, careful diet, and travel if practicable, should be recommended. Remedies directed to the treatment of symptoms connected with the nervous, circulatory, and digestive systems will be required. Of course the habit must be entirely stopped, and all thoughts of a libidinous character must be avoided. The bromides, especially the bromides of potassium and ammonium, are very useful for lessening sexual excitability in both sexes. In certain cases where these remedies, together with iron, and other appropriate drugs, have failed to diminish the frequency of the seminal emissions which are common in males, caustics may be applied to the neck of the bladder. See SPERMATORRHEA.

MATCH-MAKERS.—See OCCUPATION-DISEASES.

MATLOCK, in Derbyshire.—Thermal waters. See MINERAL WATERS.

MAW-WORMS.—A synonym for thread-worms. See ENTOZOA.

McBURNEY'S POINT.—The point midway between the umbilicus and the right anterior superior iliac spine. See APPENDIX VERMIFORMIS, Inflammation of.

MEASLES.—SYNON.: *Morbilli*; Fr. *Rougeole*; Ger. *Masern*.

A specific eruptive fever of an exceedingly infectious nature, in which the appearance of the rash is preceded by well-marked catarrhal symptoms with fever. Very few persons exposed to the infection escape, unless protected by a previous attack; a second attack before puberty is almost unknown.

The *period of incubation* lasts from eight to twelve days: it is not accompanied by any symptoms.

ÆTIOLOGY AND PATHOLOGY.—No specific micro-organism has been satisfactorily identified. When introduced into a country for the first time the disease is apt to possess a quite unwon degree of virulence, as was shown by the fact that during the epidemic in the Fiji Islands in 1875 more than one-fourth of the whole population died from its effects, while in London the usual mortality is about .5 per 1,000; this would seem to show that a considerable degree of protection can be acquired by inheritance. A second attack before puberty is very rare, but in later life subsequent attacks are not infrequently met with, and even old age does not secure exemption for one who throughout his life has shown a special susceptibility. On many occasions, however, when a person is said to have had two attacks of measles a careful investigation proves that one of the attacks was rubella, and it would be safe to assert this if the two attacks occurred in the same year. The rash is not present after death except in malignant and petechial cases, when there is a general lividity of the surface of the body and probably some swelling of the face. Judging from what has been proved in the case of enteric fever it is probable that the rash is due to the presence of the micro-organisms in the skin, and that its subsidence is due to their death. The disease is most infectious when the rash is out, next during the period of invasion, and perhaps during the whole period of incubation. It is probably not infectious during deferescence after the catarrhal symptoms have passed away. A very short exposure is all that is necessary: thus the present writer remembers a child suffering from measles being admitted for only half-an-hour into a ward full of children, with the result that four children who occupied neighbouring beds subsequently developed measles, the rash appearing in all on the same day. The disease is capable of being conveyed by personal contact, by clothes, toys, &c. Outbreaks of measles are most apt to occur either during winter or just when spring passes into summer. See PERIODICITY.

SYMPTOMS.—The *period of invasion* may or may not be ushered in with rigors or convulsions. The occurrence of these depends on the age of the patient and the severity of the attack. There is always some fever; but catarrh is the prominent feature. This is often highly characteristic, and is of great diagnostic value. It commences in the mucous membrane of the nasal cavities, and spreads in all directions, resulting in headache, sneezing, coryza, conjunctivitis, lacrymation, sore throat, hoarseness, pulmonary catarrh, with a harsh hard wheezy or croupy cough, and occasionally epistaxis. On auscultation of the chest, sibilant sounds are heard all over, the tongue is thickly coated, and vomiting or diarrhoea or both are not uncommon. The temperature generally runs up at the onset to 103° or 104° F. or even higher, but is not usually maintained at quite the same level throughout the period of invasion, a slight drop being more commonly observed. This stage lasts from three to four days, and is followed by the *period of eruption*. The rash consists at first of minute, roundish, dull-red, velvety, very slightly raised papules, which disappear under pressure; these quickly multiply and spread, running together to form irregular crescentic blotches with well-

defined scalloped edges. When thus formed the blotches are slightly darker in colour, of the tint of an unripe mulberry; they do not fade so completely or so readily on pressure; and in severe cases a slight degree of ecchymosis into them is common. The skin between these blotches is normal except in very severe cases when on the face the intervening skin may be somewhat œdematous. In the most malignant cases there may be extravasations of blood into the blotches so that the eruption becomes petechial: this form is known as 'black measles'; it is excessively rare and can only be distinguished from hæmorrhagic smallpox with great difficulty. The eruption may in rare instances be altogether absent. The rash generally makes its first appearance on the temples close to the roots of the hair, and behind the ears just below the mastoid bones, and it is these regions which should be closely examined when the rash of measles is expected. It then invades the oral circle and spreads rapidly from the temples to the cheeks, then to the rest of the face, the neck, trunk, and limbs, and is completely out in from twenty-four to forty-eight hours; it remains distinct for about three days, and then declines in the same order. The spots gradually fade, leaving brown or yellowish stains, which in the course of a few days entirely disappear, but may be followed by a branny desquamation best seen on the hands and face, as elsewhere it is masked by the natural perspiration. Some degree of stomatitis is almost invariably present. During the period of invasion even as early as the second day examination of the buccal mucous membrane may reveal numerous small red spots with a more or less well-defined blush of the surrounding parts (Koplik's spots); and sometimes preliminary rashes may be observed on the skin consisting mostly of scattered minute papules which do not run together into blotches but soon disappear, and are apt to lead the inexperienced practitioner, who may have been suspicious of measles, to declare too prematurely that his patient is not suffering from that malady. The disorder is not more severe because the rash is plentiful, or because it appears early; nor on the other hand does delay in its appearance necessarily mean that there are or will be complications. In young children the rash may be ushered in with convulsions; diarrhoea too is apt to occur with the rash. The temperature which had been inclined to fall, or may even have reached the normal during the period of invasion, rises again when the rash appears, probably even to a higher point than it reached at the onset. During the height of the rash it maintains a high level, and may even rise on the fifth or sixth days, a temperature of 105° at this period being not very uncommon, and not necessarily implying the onset of any complication; but should the fever persist after the subsidence of the rash, some complication may be confidently predicted. The frequency of the pulse is generally proportionate to the height of the fever. The catarrhal symptoms gradually increase with the appearance of the rash, and attain their height when the exanthem does, subsiding as this fades; the sibilant sounds heard over the chest are replaced by moist râles which rapidly become less abundant; the cough loses its hard character and the wheezing disappears; while the conjunctivitis and coryza also pass off. The temperature generally reaches the normal about the eighth or ninth day, and the catarrhal symptoms have usually subsided.

completely by the fourteenth. It is generally a mild affection, but all degrees of severity may be met with, and it must always be regarded as serious when it attacks a child who is already the subject of tuberculosis.

COMPLICATIONS.—Young children of neurotic tendency are very likely to have convulsions, but unless these recur frequently they need not cause alarm. Diarrhœa is common and generally unimportant, but may be so severe as to be dangerous, and this is especially likely to be the case when the development of the rash is delayed; sometimes there is a true colitis (*see COLITIS*). Acute laryngitis is occasionally met with. Bronchitis and bronchopneumonia are the most common, and in young children the most dangerous complications; pleural effusions, serous and more often purulent, are by no means uncommon. Among other complications and sequelæ the following may be mentioned: ulceration of the cornea leading to a permanent opacity; otorrhœa; otitis interna, which may or may not lead to facial paralysis; meningitis; abscess of the brain; and thrombosis of the lateral or other sinuses of the brain (*see INSANITY IN SPECIAL DISEASES*). Enlarged and caseous mediastinal or mesenteric glands with subsequent development of more or less generalised tuberculosis are among the various ultimate results, while infantile cerebral or spinal paralysis are also well recognised as occasional sequelæ. Whooping-cough seems peculiarly liable to follow in the train of measles. It is often stated that in children who have suffered from measles or scarlet fever at or before the age of three years, examination of the permanent teeth will reveal either a transverse grooving of the enamel which may be shallow or deep, or one or more spots deficient in enamel arranged transversely; these changes are best seen in the incisors and canines, and are also present in the first molars and occasionally in the bicuspid. The condition is probably due to rickets.

PROGNOSIS.—As already implied, this is generally favourable, but many things must be taken into consideration, and notably the type of the epidemic, for the severity of the attack and the liability to the different complications vary greatly in different epidemics, and every complication of course increases the danger. As a general rule it may be said that the outlook is favourable when the chest-symptoms are moderate in degree; when the exanthem is not ushered in by any great rise of temperature; when the temperature does not show much tendency to rise afterwards, and when there is not much prostration. The prognosis should be more guarded and perhaps unfavourable when the disease occurs in very young subjects, or in delicate children, especially if there is any well-marked tendency to tuberculosis, when the chest-symptoms are severe, when the rash is of a livid colour or becomes petechial; and when convulsions or any other complications supervene. There is additional danger when measles follows upon scarlet fever or diphtheria. *See MORTALITY*.

DIAGNOSIS.—Before the appearance of the rash a positive diagnosis is rarely possible except during an epidemic when the co-existence of fever with the coryza and other catarrhal symptoms would be highly suggestive, and if supported by the discovery of the characteristic eruption on the buccal mucous membrane the suspicion would be converted into a certainty. The rash may have to be differentiated

from those of scarlet fever, variola, and rubella. In regard to *scarlet fever* there should be no confusion; in this the rash is much finer, punctiform, and more evenly diffused, producing uniform redness; and there is an entire absence of the catarrhal symptoms. In *smallpox* at an early stage the difficulty may be very great, and it is sometimes necessary to wait a few hours and examine the patient again before a positive opinion can be safely reached: the points in favour of smallpox would be the history of pain in the back, the shotty feel of the papules, and the fall of temperature with the development of the rash. The eruption in *rubella* closely simulates that of measles; the temperature is, however, as a rule but slightly raised, and prodromal symptoms are slight or altogether wanting, though catarrhal symptoms may develop with the rash, and the tonsils are sometimes much swollen and more or less covered with mucus; the superficial lymphatic glands at the back of the neck, beneath the sterno-mastoid, in the axillæ and in the groins are enlarged and hard; this is a very characteristic sign and an early one, and has been recognised even a week before the eruption.

TREATMENT.—In a case of uncomplicated measles good nursing is alone necessary, the greatest possible care being taken to avoid chill. When there are other children in the family, the attempt should always be made to completely isolate the sick child, and the popular theory that the others had better take the disease and have done with it should receive no practical support from the medical practitioner; but as a matter of fact, inasmuch as the children have been together during the whole period of incubation and often during the best part of the period of invasion as well, the mischief is done before isolation can be attempted, and it is a not uncommon experience, where there are three children in the family, to find the second child develop measles about twelve days after the first, and the third after the expiry of another similar interval. The quarantine-period after a child has been exposed to measles before he is allowed to go back to school or mix with other children is sixteen days, disinfection of the child and his clothes having been carried out immediately after exposure and again at the termination of the quarantine (*see INCUBATION*). A child who has had measles may go home or go back to school in not less than three weeks from the date of the appearance of the rash, provided that all catarrhal symptoms are over and that his clothes have been thoroughly disinfected—the latter by baking or superheated steam after dipping in carbolic acid. The personal disinfection of the patient involves being washed from head to foot in a warm bath with carbolic-acid soap, especial attention being paid to the scalp and hair. *See DISINFECTION*; and *PUBLIC HEALTH*.

MEAT, Poisoning by. — *See FOOD, POISONOUS*.

MECKEL'S DIVERTICULUM.—*See INTES-TINES, Diseases of*; and *INTESTINAL OBSTRUCTION*.

MEDIASTINUM, Diseases of.—The term mediastinum is applied to the central region within the thorax which is bounded by the mesial folds of the pleura. It thus contains the heart, pericardium and great vessels, the vagus, phrenic and cardiac

nerves and plexuses, the thymus gland or its remains, the trachea, œsophagus and thoracic duct, certain lymphatic glands and vessels, and the connective tissue in which these structures are embedded. All diseases affecting these various structures might thus be described as diseases of the mediastinum, but the affections of the different organs are described elsewhere in the special articles dealing with them respectively. In the present article reference will be made only to the following conditions: (1) acute and (2) chronic inflammation of the mediastinal connective tissue, and (3) tumours growing within the thorax, including those arising primarily in the lung. For hernia occurring into the mediastinum, reference may be made to pp. 386 and 682.

1. Acute Suppurative Inflammation. — SYNON.: Abscess of the Mediastinum.

ÆTIOLOGY AND PATHOLOGY.—It is probable that occasionally inflammation of the connective tissue of the mediastinum may run its course without suppuration, but of this condition little is known. In cases of death from pleurisy and pericarditis there may be found at the necropsy some extension of the inflammatory process to the tissues of the mediastinum, and it is probable that, in patients who recover, such an extension may have taken place, the mediastinal inflammation subsiding along with that of the serous cavity. In some cases acute mediastinitis may perhaps pass into a chronic condition, giving rise to the mediastinal fibrosis treated of in the next section.

The two commonest causes of mediastinal abscess are direct traumatism in the form of blows upon the chest or penetrating wounds, and acute inflammation, septic or tubercular, of the lymphatic glands of this region. Inflammation may spread from above, as from a tracheotomy-wound, a retropharyngeal abscess or cellulitis of the neck. Disease of the sternum may result in abscess-formation in the connective tissue behind this bone, and disease of the vertebræ may similarly involve the posterior mediastinum. Erysipelas, pyæmia and acute specific fevers may occasionally give rise to mediastinal abscess; and suppuration in the thymus gland may occur without clearly assigned cause. Perforation of the œsophagus by a foreign body or malignant growth, or rupture of a diverticulum from this canal, may cause suppuration in the posterior mediastinum. Apart from these last cases, the anterior portion of the region is the most common seat of abscess. When pus has once formed it is liable to infect the pericardial or pleural cavities; or it may burst into the œsophagus, trachea, bronchus or lung; or 'point' externally upon the thoracic wall.

CLINICAL PHENOMENA.—The presence of suppuration in the mediastinum may not give rise to any very characteristic symptoms or physical signs. The general phenomena accompanying suppuration in any part of the body will be present, viz. pyrexia of a hectic character, sweating, and chilliness or actual rigors. In some cases there is pain referred to the region behind the sternum or to the back, and there may be some tenderness on percussion over the affected area. If the collection be of any size symptoms of pressure may arise, such as cough, stridor, and dyspnoea; the patient may be unable to lie on one or other side, or continuous orthopnoea may be present. If the anterior mediastinum be the seat of the abscess there may be fullness over

the region of the sternum, and dulness upon percussion over this region. A localised swelling, with œdema and redness, may appear in one of the intercostal spaces, and this may even pulsate owing to the contiguity of the collection of pus to the heart or aorta. In other cases 'pointing' of the abscess may occur at the root of the neck above the manubrium sterni.

DIAGNOSIS AND TREATMENT.—In presence of bone-disease or other cause of inflammation liable to extend to the mediastinum symptoms of pressure within the chest may lead to a suspicion of this condition, otherwise the recognition of mediastinal suppuration is difficult or impossible. The appearance of a fluctuating swelling, due to this cause, upon the chest-wall could not be distinguished with any certainty from the pointing of a localised empyema. The possibility of confusion of a pulsating abscess with an aneurysm should be borne in mind. The ideal treatment of suppuration in the mediastinum, as elsewhere, is evacuation of the pus by surgical measures. When the abscess is situated in the anterior mediastinum these should not present any insuperable difficulties. The sternum might be trephined if necessary to secure an efficient opening. Even in the posterior mediastinum, if the existence of an abscess were certain and the presence of malignant disease could be excluded, it is probable that an attempt should be made to evacuate the pus. If there be a probability only of the existence of suppuration, without definite signs of its occurrence, hot fomentations to the chest may relieve pain, the previous application of leeches also being advantageous as a temporary measure.

2. Chronic Inflammation. —SYNON.: Chronic mediastinitis; Indurative mediastino-pericarditis.

ÆTIOLOGY.—Of the causation of this condition nothing is certainly known. A chronic fibrosis such as is here found must be the result of the presence of an irritant of low intensity acting over a considerable period of time. It is possible that in some cases a rheumatic pericarditis may be the starting-point of the trouble, the inflammation spreading from the serous sac to the surrounding connective tissue. Minor degrees of such 'internal and external pericarditis' are not infrequently met with, without any considerable involvement of the mediastinal areolar tissue. In other and more numerous cases it seems probable that the lymphatic glands of the mediastinum, especially the bronchial glands, are the part first affected, the periadenitis associated with the glandular inflammation extending as a cellulitis to the surrounding regions. Thus cases appear to owe their origin to measles or whooping-cough, which are known to be associated with glandular enlargement. To this cause are probably due the instances in which the mediastinum suffers alone without the pericardium, and it is not impossible that the pericarditis may in other cases be secondary to the inflammation outside the sac. A certain proportion of the cases are probably tubercular in origin. The possibility of syphilis, congenital or acquired, as a causal agent may be suggested. Males are affected far more frequently than females. Thus, of 40 recorded cases 33 were males and only 7 females. It is probable that the affection usually originates in childhood, but that the rate of its progress to a fatal issue is very various, many of the cases dying in childhood or youth, others in early adult life, and a few reaching middle or advanced age.

PATHOLOGY.—The lesion consists in the formation throughout the mediastinum of a dense mass of fibrous tissue, which binds the contents firmly to one another and to the walls of the chest. The mediastinal affection is generally associated with pericarditis (*mediastino-pericarditis*), and often with pleurisy of one side or both. In course of time as the fibrous tissue contracts various morbid effects are produced. The organ most notably affected is the heart. In well-marked cases the two layers of the pericardium are firmly united, and the outer layer is also adherent to the back of the sternum. The heart is thus much hampered in its action, while at the same time the tight coat of fibrous tissue in which it is enclosed prevents it from undergoing the enlargement necessary to compensate for the increased work thrown upon it. Failure of the heart consequently results. The organ is often found *post mortem* to be rather smaller than normal, and the walls may have undergone fatty or fibrous change. The veins traversing the mediastinum are liable to injurious constriction, and thrombosis may take place within them. The liver is much enlarged, partly owing to failure of the heart, partly perhaps to constriction of the inferior vena cava at its entrance into the pericardium. It is also frequently the seat of a process of cirrhosis, the cause of which is not clear, but which may be in part due to the chronic venous congestion, and in part to extension of inflammation from the overlying peritoneum (perihepatitis). Owing to these causes ascites is a marked feature, preceding and being out of proportion to the general cedema which occurs towards the end. The pleuræ may be the seat of considerable effusion, either of an inflammatory or a dropsical character. Collapse of the lung may result. Pulmonary emphysema is not an infrequent feature in these cases, and infarction may also be found *post mortem*. The kidneys may be the seat of interstitial nephritis, or may suffer merely from congestion due to cardiac failure.

In one case which occurred in Charing Cross Hospital it appeared that an acute attack of inflammation had supervened upon the chronic condition. Thus, in addition to the fibrosis of the mediastinum and obliteration of the greater part of the pericardial cavity, there was found a collection of pus in the remaining pocket of the pericardium, recent pleurisy and acute inflammation of the bronchial glands.

CLINICAL PHENOMENA.—The onset of the disease is insidious and the condition cannot be recognised until the process of mediastinal fibrosis is far advanced. Suspicion may first be aroused by the existence in a child or young person, in whom alcoholism is improbable, of great enlargement of the liver and some degree of ascites; or the symptoms may consist of breathlessness and signs of heart-failure without signs of valvular disease. Examination of the chest may reveal an enlarged area of præcordial dulness, extending upwards behind the sternum; but this may be masked by the existence of emphysema. The special signs which may be produced by the pericardial adhesions are displacement outwards of the apex-beat without the presence of murmurs which would account for cardiac dilatation, fixity of the position of the apex-beat when the patient changes his posture, retraction of the chest-wall with systole, and the existence of a pulse which remits with inspiration (pulsus

paradoxus). Venous fulness and pulsation may be seen in the neck. As the case proceeds swelling of the legs occurs, and later on general anasarca, the face and chest being involved. Effusion may occur into the pleural cavities. Dyspnoea and cyanosis become prominent features, and death occurs from exhaustion. The urine towards the end is scanty and albuminous. Life is not likely to be prolonged much beyond eighteen months after the signs of the condition are fully developed.

DIAGNOSIS.—Great enlargement of the liver in a young person along with some ascites and dyspnoea, and apart from obvious causes of cardiac failure or hepatic disease, may cause a suspicion of the existence of mediastinitis; the existence of an enlarged area of præcordial dulness, if present, would be a further indication of this condition, but its absence does not exclude mediastinal fibrosis. The signs peculiar to the condition of external and internal adhesion of the pericardium should also be sought for; and Harris lays stress upon inspiratory filling of the veins in the neck as of importance if present. The progressive nature of the symptoms and the occurrence of general dropsy and pleural effusion will confirm the diagnosis.

TREATMENT.—Nothing can be done to arrest the process of fibrosis in the mediastinum, and treatment must therefore be directed merely to the relief of symptoms. The patient need not be kept in bed, apart from the occurrence of dyspnoea and palpitation, but care must be taken against the occurrence of chill. Any bronchitis present must be treated on ordinary lines, and cardiac failure may be met by digitalis, nux vomica, and ammonia. The ascitic and pleural effusions must be drained as they accumulate, and incisions made in the legs may give considerable temporary relief when general cedema is present.

3. Tumours of the Mediastinum, and of other intrathoracic structures.—**VARIETIES.**—The most common tumours which originate primarily in the mediastinum are lymphosarcomata, starting in the lymphatic glands. These are generally soft rapidly growing tumours, composed of small round cells with a scanty intercellular fibrous stroma. They often reach a large size, and at the time of death may weigh several pounds. In rarer instances the connective tissue is a larger amount, and the growths are firm, tough, and fibrous. Fibrosarcoma (spindle-celled) may also occur, and simple fibroma. Primary carcinoma cannot arise apart from growths originating in the epithelium of the special organs contained within the thorax (œsophagus, thymus gland, bronchi, &c.), but alveolar sarcoma may be found, indistinguishable microscopically from true cancer. Chondromata may grow from the walls of the chest, and mixed tumours containing cartilage may originate in the thymus gland. Malignant tumours of the lung, œsophagus, trachea, thymus, and bones may spread to the mediastinum; and secondary deposits may occur there in cases of malignant growths elsewhere, especially carcinoma of the mamma. Sub-pleural fibromata and fibrosarcomata, as they enlarge, encroach on the area of the mediastinum.

Aneurysm of the aorta or great vessels, hydatid cysts, and enlargements of the lymphatic glands, due to tuberculosis, syphilis, or lymphadenoma, are sometimes classed as tumours of the mediastinum, since they give rise to similar phenomena of pressure; but these conditions are not treated of in the

present article. See AORTA, Aneurysm of; BRONCHIAL GLANDS, Diseases of.

New-growths occurring in the lung.—The commonest primary growth met with in the lung is carcinoma, originating in the epithelium of the bronchi or alveoli. It is generally of the soft variety, known as encephaloid; and secondary growths occur in the bronchial glands and along the lymphatics. The growth may form a mass weighing several pounds. Many of the connective-tissue tumours may be found in the lungs, but these are small, rare, and innocent. Secondary deposits in the lungs are most frequently multiple and bilateral. Sarcomata are the commonest source of such growths, but carcinomata may also give rise to metastatic deposits in these organs, and the uterine tumour known as deciduoma malignum not infrequently does so. Hæmorrhage often occurs into such nodules; or if they are slow in growth cavities may form by breaking down of their substance. Endotheliomata may affect the pleura primarily, giving rise as a rule to a number of well-defined white fibrous thickenings. Growths which originate in the pleura, or involve it by extension or metastasis, are generally accompanied by pleural exudation; this is often hæmorrhagic in character. Secondary growths frequently escape observation when they start at the root of the lung, and gradually invade the organ along the course of the bronchial tubes and vessels.

EFFECTS AND CLINICAL PHENOMENA.—The most important effects produced by tumours growing within the mediastinum are due to the pressure exerted upon the important structures in the neighbourhood; but the extent to which this occurs varies considerably with different kinds of tumour. Thus a firm, well-defined growth, even if quite small, will tend to produce serious pressure-effects, while a soft infiltrating neoplasm may reach a large size before such a result occurs, since it insinuates itself between other structures without compressing them.

The large *veins* within the thorax are often early affected, and thrombosis may occur within them as a result of slowing of the blood-current. Their walls are sometimes invaded by malignant tumours, especially carcinomata. *Edema* results in the parts drained by the affected vein, and is thus frequently met with in one or other upper extremity, in the neck and face, and on the thoracic walls. Enlargement of subcutaneous veins may occur in the course of the establishment of a collateral circulation; and this is most evident when the superior vena cava is seriously compressed, the blood being then compelled to find its way to the heart through the inferior vena cava. The superior epigastric veins and anterior branches of the lumbar veins become enlarged and tortuous; and by pressure upon different parts of these vessels it is possible to ascertain that the current of blood within them is flowing from above downwards.

Serious pressure upon the *arteries* within the thorax is not very frequently met with, but rarely an artery may be perforated by a malignant growth, and occasionally abnormal bending of one of these vessels may interfere with the current of blood within it. Alteration in the size and force of one of the radial pulses may thus occur.

The *heart* may be considerably displaced by a large new-growth, and serious embarrassment of its action may thus be produced. A murmur may

sometimes result from such displacement. The extent to which this organ is displaced is not, however, necessarily proportionate to the size of the tumour. A small growth, situated at the base of the lung, may push the heart noticeably out of its normal position, whereas a large infiltrating tumour may cause little or no alteration in the relation of the heart to the chest-wall. The pericardium may be penetrated by an advancing tumour, and pericardial effusion result; even the walls of the heart may be invaded in rare instances.

The *œsophagus* may be compressed by a tumour suitably situated, and dysphagia may result. This, however, is a very uncommon occurrence; and if difficulty in swallowing is an early and prominent symptom, it is almost certainly due to the presence of primary cancer of the œsophagus. Pressure upon the *thoracic duct* may cause dilatation of the receptaculum chyli, and some escape of chyle from the lacteals into the peritoneal cavity.

Pressure upon the *trachea* or *bronchi* is an important effect of intrathoracic growths, resulting in shortness of breath, and frequently in the occurrence of noisy respiration (stridor). The latter may be either audible at a distance from the patient, or only discoverable upon auscultation of the chest. *Dyspnoea*, due to direct pressure upon the air-passages, is generally continuous; its origin is gradual, and toward the end of the case extreme distress may be produced. The rate of respiration is generally increased. Deficient entry of air into some portion of the lung, or collapse of this area, may result from the pressure, and actual broncho-pneumonia may occur. The trachea may be displaced to one side by tumours growing at the upper part of the thorax. *Dyspnoea* may also result from pressure upon nerves supplying the bronchi or from cardiac disturbance. In such cases it is generally paroxysmal, the attacks resembling those of spasmodic asthma. *Dyspnoea* is often increased by the existence of pleural effusion and by displacement of the heart.

Pain may be produced by pressure upon *sensory nerves*; and this may be referred to the thorax beneath the sternum or to the back, or may radiate round the chest and down the arm. It is generally neuralgic in character, but a constant boring or aching pain may occur in cases where erosion of bone is taking place. This is not frequent, but may be met with in cases of carcinoma. Tenderness of the thoracic wall is not infrequently present. Of *motor nerves*, the recurrent laryngeal is most often paralysed, resulting in loss of movement in one vocal cord, with hoarseness or actual aphonia, and the peculiar ineffectual cough characteristic of laryngeal paralysis. The phrenic nerve may also be interfered with, and immobility of half the diaphragm may result, or in rare cases hiccup due to irritation of the nerve. Pressure upon the sympathetic chain may cause alteration in the size of one pupil; and involvement of the vagus may induce attacks of cardiac disturbance, and also be associated with pneumonic changes in the lungs, considered by some authorities to be of a 'trophic' nature. Very exceptionally a malignant growth may invade the spinal canal and produce symptoms of pressure upon the cord.

Cough is almost invariably present at some stage of the affection, and often becomes progressively more troublesome; but the prominence of this symptom differs in individual instances. In cases of tumours of the lung, and in presence of much

co-existent bronchitis or of pressure upon the air-passages, cough is constant throughout; in the last case it is often stridulous in character. If it be due to irritation of nerve-trunks it is paroxysmal and of a 'brassy' quality: it may be to some extent proportionate to the size of the tumour. There is not usually much *expectoration*, apart from the presence of tuberculosis of the lung, as a complication, or of bronchitis. Copious expectoration is suggestive of a primary growth in the lung. As the case advances *cytosis* is usually a marked symptom, and this, along with the œdema of the neck, face, and upper part of the thorax, may give the patient a very characteristic appearance. A peculiar variable or intermittent *temperature* is sometimes observed, attacks of pyrexia occurring either irregularly or at more or less constant intervals of a few days. Fever may, however, be absent throughout the illness.

The phenomena discoverable upon physical examination of the chest, in addition to those already mentioned, vary with the size and position of the tumour. Alterations may occur in some cases in the shape of the thorax, which may show a local bulging over the growth, the sternum or rib-cartilages being pushed forward, or a depressed area due to collapse of some portion of the lung. The growth may invade the chest-wall and project beneath the skin. In such circumstances pulsation may sometimes be observed if it be very vascular, as in some forms of sarcoma. Dulness on percussion will be found over the tumour when this is directly beneath the thoracic wall, and in the case of tumours growing in close relation with the bronchi, tubular breathing will be audible in the dull area; but if the air-passages be occluded there will be deficient movement with absence of vocal and respiratory sounds over the affected portion of lung. Enlarged glands are frequently discoverable above the clavicles in cases of malignant intrathoracic tumours. The liver and spleen may be displaced downwards into the abdomen by the pressure of very large growths, and the movement of one or other of these organs and of the abdominal walls in respiration may be defective in case of paralysis of the diaphragm.

In the case of *tumours of the lung* itself, there is not often any bulging of the chest-wall: with slowly growing tumours there may even be retraction of the chest, especially if pressure upon the air-passages has led to collapse of part of the lung. Respiratory movement is usually defective over the affected area. The dulness found upon percussion is absolute in degree—of the character often described as 'wooden'—and accompanied by marked increase in resistance. Its distribution is irregular: extension across the middle line of the sternum is a valuable diagnostic sign of the existence of a tumour. The co-existence of pleural effusion may in some cases complicate the diagnosis. Vocal fremitus may be normal or increased; if a large bronchus be compressed it may be entirely absent. Breath-sounds are frequently absent over a tumour of the lung, but bronchial breathing may be found. If degenerative changes be taking place in the growth, or if there be accompanying bronchitis, râles may be audible. Stridor is not so likely to occur as in tumour of the mediastinum; and dyspnoea is seldom so intense as in that condition.

There is generally slight continuous pain, accompanied by loss of flesh, anæmia, and weak-

ness. Cough is generally present, sometimes from an early period; and the sputa may be hæmorrhagic: they are not infrequently of a consistency and appearance which have been compared to 'red-currant jelly.' Profuse hæmoptysis sometimes occurs.

No *age* and neither *sex* is free from liability to mediastinal tumours, but they are more common in males than in females, and primary growths are most frequently met with in early adult life. The duration of the disease varies with the position and rate of growth of the tumour. In cases of 'simple' growths, two years may perhaps be taken as an average duration, but much longer cases are recorded. Malignant growths are usually much more rapidly fatal. Death occurs either by increasing dyspnoea and exhaustion, by hæmorrhage, due to perforation of a vessel or by implication of the heart and pericardium. Secondary growths may occur in other organs, such as the brain, and prove fatal; in one case, seen by the writers, the symptoms first complained of were those of paralysis, due to secondary growths in the brain, the phenomena due to the primary intrathoracic tumour only developing later.

DIAGNOSIS.—It is necessary not only to recognise the existence of a cause of abnormal pressure within the thorax, but also to distinguish true new-growths from aneurysms and glandular swellings, which may produce similar effects. By far the most common cause of intrathoracic pressure is aneurysm of the aorta, and the possibility of its presence should be carefully eliminated before arriving at a diagnosis of mediastinal tumour. Aneurysm is far commoner in males than in females, and occurs chiefly in adult life (35–50 years), and in those who have followed laborious occupations: on the other hand, new-growths occur in much younger subjects, and the proportion of women affected is relatively much larger. The position of an aneurysm is necessarily limited to the course of the great vessels, and the area of dulness produced by it upon the thoracic wall is not often large, whereas new-growths may occur at any part of the thorax, and may cause very extensive impairment of resonance. It is not often that tumours cause marked local bulging of the chest, nor do they frequently pulsate to an extent really comparable with that of aneurysms. The growth of a malignant mediastinal tumour is much more rapid than that of an aneurysm; and the occurrence of secondary deposits and enlarged glands may place the existence of the former beyond doubt. The pressure produced by a tumour is much more frequently exerted upon the venous trunks of the mediastinum than is that of an aneurysm, while, on the other hand, the œsophagus is much less frequently affected. Affection of the right recurrent laryngeal nerve and right sympathetic chain could hardly be produced by an aortic aneurysm; aneurysm of the innominate artery may, however, involve these structures. Dyspnoea is on the whole less frequent in cases of aneurysm than in those of new-growths; and the latter are generally accompanied by anæmia and general constitutional disturbance, not met with in the vascular disease. Irregular pyrexia is in favour of mediastinal tumour, but may be met with in cases of tubercular or lymphadenomatous enlargement of mediastinal glands. It is rare, however, for these to be primarily affected in Hodgkin's disease, the glands in the neck, and often those in the

groin and elsewhere, being enlarged in these patients. Tuberculous glands are not likely to cause symptoms of pressure except in young children (see BRONCHIAL GLANDS, Diseases of). The use of the X-rays is often of considerable service in diagnosis. If the patient's chest be examined with the fluorescent screen, a tumour will produce as dense a shadow as an aneurysm, but the latter can be distinguished by its pulsation and to some extent by its position and shape. It is difficult, however, to distinguish infiltrating growths and scattered nodules from tubercular masses. Fluid in the pleural cavity, and still more a thickened pleura, will obstruct the X-rays, but never to so great an extent as a tumour; the latter also has a more distinct edge than any pleural condition except a localised empyema, which is not likely to give rise to a difficulty of diagnosis. See RÖNTGEN-RAYS.

Tumours originating in the lung and giving rise to no pressure-symptoms have to be distinguished from tuberculosis. In addition to the use of the X-rays just alluded to, there is generally absence of fever, and of tubercle-bacilli from the sputum. The progress of the disease is rapid and continuous, the physical signs extend over a large area, and enlargement of superficial lymphatic glands occurs. Physical signs resembling pleural effusion but with some marked inconsistency and with absence of fluid on exploratory puncture are in favour of the presence of a new-growth. Should actual pleural effusion be present a hæmorrhagic character is in favour of tumour involving the pleura: masses of large swollen endothelial cells may be found in some cases upon microscopical examination of the fluid. The possibility of the co-existence of tubercular disease of the lung with a tumour of the mediastinum, as well as with aneurysm, must be borne in mind, since otherwise the conjunction of symptoms produced may be puzzling.

PROGNOSIS.—The outlook is probably hopeless in all cases in which it is possible to be certain of the existence of a tumour within the thorax. The duration of life will depend upon the nature of the growth and its relation to important intrathoracic structures.

TREATMENT.—Since any growth within the chest is beyond the reach of surgical intervention, all that can be attempted is the relief of distressing symptoms as they arise. Even this object can, unfortunately, be only imperfectly attained. Opium or morphine may be administered without hesitation in view of the necessarily fatal termination of the disease, and much relief may thus be obtained, not only of the pain caused by the growth, but also of the cough, which is frequently both distressing and ineffectual. There is no advantage to be gained by keeping these patients in bed, at least in the earlier stages of the disease: the feelings of the patient are the best guide to follow. Later, as dyspnoea becomes more urgent, rest in bed will become compulsory, and the upright position with a bed-rest or additional pillows is generally found the easiest. Tracheotomy can hardly ever be advisable, however urgent the dyspnoea, since the obstruction is below any point which can be reached; in a very few cases associated with laryngeal spasm it may afford relief. If extreme dysphagia result from pressure upon the œsophagus, the question of the performance of gastrostomy will arise. Authorities differ as to the advisability of removing pleural effusion when it occurs. In many cases its presence

seriously adds to the difficulty in breathing, and there is no valid reason for not removing it by aspiration, an operation which may afford great temporary relief to the sufferer, and may be repeated as often as the fluid reaccumulates. Inhalations of oxygen may be called for if cyanosis becomes a prominent symptom, due to pressure upon the respiratory apparatus. Careful nursing is requisite in protracted cases to avoid the formation of bed-sores.

MEDULLA OBLONGATA, Lesions of. SYNON.: Fr. *Maladies de la Moelle Allongée*; Ger. *Krankheiten des verlängerten Marks*.

INTRODUCTION.—The pathology of the medulla oblongata is more than usually complex. Not merely is it liable to injuries, and diseases such as hæmorrhages, softenings—necrobiotic and inflammatory, tumours, &c., having their primary seat there, as in other nerve-centres; but also, and more frequently, the medulla is implicated in diseases of the pons and cerebellum, and affected indirectly by intracranial diseases in general. Being the connecting isthmus between the brain and spinal cord, it is subject to ascending or descending degenerative processes, secondary to lesions in the spinal or cerebral sensory and motor tracts. Further, it is the seat of a chronic form of degeneration, characterised by a very definite group of symptoms, differentiated under the term 'bulbar or labio-glosso-laryngeal paralysis.'

With the indirect affections of the medulla oblongata, in connection with the various forms of intracranial disease, degenerations of the motor or sensory tracts secondary to cerebral or spinal disease, or the pathology and symptomatology of bulbar paralysis, this article does not profess to deal, as these subjects will be found fully discussed under their respective headings. Attention will be directed mainly to the data which serve to establish, so far as this is possible, the regional diagnosis of medullary lesions.

SUMMARY OF PATHOLOGICAL CONDITIONS.—*Traumatic lesions*.—Injuries of the medulla oblongata are not uncommon in consequence of fracture or dislocation of the atlas and axis, as in falls, hanging, twisting of the neck, or as the result of diseased vertebræ. In such cases death is instantaneous, owing to the sudden cessation of the circulation and respiration, from lesion of the centres for these vital functions, which are situated in the medulla.

To commotion or contusion, with punctiform extravasations in the medullary centres, Duret attributed sudden death from blows on the head. Not infrequently lesions of the fourth ventricle, the result of cranial injuries, not proving fatal, give rise to diabetes mellitus or insipidus, along with other symptoms indicative of chronic lesion of the pons or medulla.

Effusions of blood into the fourth ventricle,

whether arising from the medulla itself, the pons, or the cerebellum, or gaining access from the lateral ventricles by the aqueduct of Sylvius, are, as a rule, suddenly fatal from paralysis of the circulation and respiration. Death may occur with or without convulsions.

Tumours.—Tumours implicating the medulla oblongata may have their seat primarily in the medulla; but more commonly the growths are situated at the base of the skull, in the cerebellum or pons, and invade the medulla in their growth. Besides the special localising symptoms of medullary disease, there are general symptoms of intracranial new-growth; of these vomiting is usually pronounced, and optic neuritis rare. Here also, however, some remarkable cases have been put on record, in which, notwithstanding the existence of tumours actually in the substance of the medulla itself, the symptoms during life have presented nothing striking or characteristic.

Hæmorrhage.—Hæmorrhage into the substance of the medulla oblongata, and limited to this, is comparatively rare. More commonly the pons and medulla are affected together. Hæmorrhages here of any extent are very rapidly fatal. In some cases death is instantaneous. In others a few hours may elapse, death occurring in profound coma with stertorous respiration and occasionally convulsions. Whether the hæmorrhage is primarily in the medulla or in the pons cannot be diagnosed with certainty. The other causes of sudden death, such as affections of the heart, must be excluded before hæmorrhage into the medulla can be diagnosed, and this is in many circumstances obviously impossible.

Hæmorrhage into the medulla oblongata is usually fatal, and rarely gives rise to chronic stationary lesions. These are commonly the result of thrombosis or embolism, or, more rarely, acute myelitis.

Thrombosis.—Thrombosis of the vertebral arteries and their branches is the most common origin of softening limited to the medulla oblongata. The onset is frequently sudden, as in hæmorrhage, but the course is more slow. The more chronic nature of the affection is an important diagnostic feature of softening. The symptoms of softening of the medulla thus arising are in many respects like those of progressive bulbar paralysis, but there are also important differences. They are sometimes generalised under the head of 'acute' or 'apoplectic-form' bulbar paralysis, in contra-distinction to the chronic degenerative form of this affection described by Duchenne. See LABIO-GLOSSO-LARYNGEAL PARALYSIS.

LOCALISING PHENOMENA.—The symptoms met with in the affection just named are the most reliable clinical data on which to found a regional diagnosis of lesions of the medulla oblongata. The characteristic symptoms are a conjoint affection of the extremities and one or more of the bulbar cranial nerves, with impairment of speech and deglutition, and cardio-respiratory disturbances. Sometimes all four extremities are paretic or paralysed; sometimes the lower extremities alone; and occasionally the paralysis is of the hemiplegic order. If the paralysis affects only the extremities, without implication of the bulbar nerves, as sometimes occurs, a diagnosis of the medullary seat of the lesion cannot be made with certainty.

Of the cranial nerves the hypoglossal is most commonly involved. The symptoms are impaired

mobility of the tongue, with more or less pronounced dysarthria (see APHASIA). This is not absolutely characteristic of bulbar disease, however, as a similar affection of the hypoglossal may occur in disease of the pons. But a form of crossed paralysis, palsy of the limbs on one side and of the tongue on the opposite side, is probably pathognomonic of coarse disease within the medulla. The tongue and speech are rarely, if ever, so affected as in the classic or progressive bulbar paralysis, nor has the atrophy of the muscles of the tongue, with altered electrical reactions, been noted.

Of more importance as a diagnostic mark is dysphagia, or paralysis of deglutition. This, in the absence of general cerebral symptoms, points to affection of the medulla. Paralysis of the soft palate, on one or both sides, is also a frequent, if not constant, symptom. Occasionally also aphonia occurs, and, taken with the other symptoms, points conclusively to affection of the medulla oblongata.

Irregularity of the heart; acceleration or retardation of the pulse; and sighing and laboured respiration, often amounting to orthopnoea, in the absence of general cerebral symptoms, are also important indications of disease of the medulla oblongata. Among other symptoms have been noted coughing and vomiting, explicable by affection of the respiratory centres. Trismus has been mentioned by Joffroy as a characteristic symptom of acute bulbar paralysis, but Nothnagel, on good grounds, disputes the accuracy of this statement.

A case recorded by Glynn, where a tiny tumour (glioma) was found *post mortem* in the middle line of the medulla at the level of the calamus scriptorius, showed many of the above-mentioned symptoms, the most prominent being intense dyspnoea with paralysis of the diaphragm, vomiting, impaired movement of lips and tongue, dysphagia, loss of reflex action of palate, weakness in both arms and less in legs, and a trace of sugar in the urine.

Albuminuria and glycosuria have also been observed in connection with bulbar lesions, the latter more particularly after injuries affecting the floor of the fourth ventricle; but the occurrence of these symptoms in connection with acute bulbar paralysis requires further investigation, as they cannot as yet be regarded as constant.

An affection simulating disease of the medulla oblongata results from bilateral cortical or sub-cortical disease, giving rise to a condition of double hemiplegia. Such a bilateral lesion causes paralysis of articulation, and also true aphasia if the lesion is cortical, along with a greater or less degree of paralysis of the limbs. The diagnosis must depend on the truly volitional character of the paralysis in such cases, the reflex mechanism of deglutition being unimpaired. There will also be absence of affection of sensibility and of trophic degeneration of the muscles, and absence also of disturbances of the cardiac and respiratory rhythm. Defective comprehension of speech, and obvious aphasia—the movements of articulation not being absolutely paralysed—and also agraphia—the hand not being completely powerless—will differentiate cerebral from bulbar paralysis.

Lesions in the neighbourhood of the pyramidal decussation, though rare, have a characteristic symptomatology. This consists of anæsthesia over the distribution of the fifth cranial nerve on the side of the lesion, with paralysis of the limbs on the

same side, and analgesia of the body and limbs on the opposite side: an association which has been experimentally found to be due to destruction of the tubercle of Rolando.

SPINAL CORD, Diseases of.

MEDULLARY CANCER.—A synonym for encephaloid cancer. See CANCER.

MEGRIM.—SYNON.: Migraine; Sick Headache; Nervous Headache; Hemicrania (ἡμί, half; and κράνιον, the head); Fr. *Migraine*; Ger. *Migräne*.

DEFINITION.—Headache of a periodical character; generally ushered in by some premonitory symptoms; more or less unilateral; and frequently associated with nausea and bilious vomiting.

ÆTIOLOGY.—The chief predisposing causes of attacks of megrim are hereditary tendency; anæmia; a general want of tone in the system; and the nervous temperament. Among the exciting causes may be included all those of a depressing or exhausting nature, whether physical or mental, such as prolonged mental work, mental excitement, grief, anxiety, bodily fatigue, late hours, sexual excesses, breathing the impure air of a crowded room, and improper food.

SYMPTOMS.—This complaint seems to have two more or less well-defined stages, the headache being preceded for a variable period by certain disorders of sensation. In some persons the malady stops short here, and is not followed by headache; in others the headache appears to be developed without any premonitory symptoms, until careful inquiry reveals the contrary. The two stages therefore are, first, the stage of disordered sensation; second, the stage of headache, with other symptoms.

The most striking of the disordered sensations is a transient disturbance of vision which sometimes takes place. It commences with a wavy glimmering near the outside corner of the field of vision, and spreads all over the visual area with a zigzag outline, in a straight-lined angular pattern, and with or without lines of colour between the darker lines. Or it may commence by the appearance of a blind spot close to the centre of vision, which soon begins to spread, showing a serrated margin, and presenting a tremor or wavy glimmering in its interior. This condition is often associated with a feeling of chilliness, coldness of the hands and feet, or other symptoms; it may last from five to thirty minutes or longer, and then be succeeded by the stage of headache.

On the other hand, the headache may be, and in many individuals always is, developed without the ocular disturbance, but other sensations are substituted for it. The patient has a feeling of chilliness, and the feet are cold. There is mental depression, with a dread of impending evil; the patient is restless and uneasy; 'cannot quite tell,' as he says, 'what he would be at'; and has what is expressively called 'the fidgets.' This condition may continue half an hour or more, and then the

slight boring piercing pain is felt in the head, with which the aching begins; and the disorder runs its course, as will be presently described. In other cases, this feeling of depression or uneasiness lasts for several hours, the patient goes to bed, and in the early morning wakes with the headache fully developed.

The headache, when preceded by ocular disturbance, shows itself as follows: When the vibratory movement is at its height, a little aching is felt in the head, on the side *opposite* to that on which the glimmering first appeared; it is slight at first, but gradually increases in intensity. Some persons have said that the sensation was as though a point in the temple were being bored with a gimlet, and the gimlet slowly increasing in size. The pain gradually spreads from this point, which may be covered with the finger, and pressure upon which affords relief, first over one side of the head; and then, but not always, it extends to the other. As the headache increases, the ocular disturbance declines; nausea is felt, which increases with the headache; retching and vomiting occur, the latter sometimes, though rarely, giving relief; the head throbs; the slightest movement increases the pain, and any attempt to move from the recumbent posture increases the gastric uneasiness; the mouth feels clammy; the eyeballs ache, and are tender on pressure, one more so than the other; the pupils are rather contracted, and generally unequally so; and the patient lies apparently more dead than alive, his face pale, and the head hot. After a varying number of hours he is somewhat relieved by troubled sleep; he wakes up next morning, free perhaps from headache; but he is listless; his brain is weary; and he feels as if he had undergone a hard mental struggle. There may be now an interval of a few days, weeks, or years, before the disorder again shows itself.

The headache varies much in character, degree, and duration. In some persons the pain is not localised in any particular spot, but seems generally diffused over the head; others have not noticed that there is more pain on one side of the head than the other, or that the aching radiates from one painful spot, until their attention has been directed to the fact, and then they distinctly recognise it; others, again, have neither vomiting nor nausea; and lastly, the duration of the headache may be very short, or not extend over more than two or three hours, or this symptom may be entirely absent. The disorder may even stop short at the vibratory stage, the vision be restored, and no further inconvenience felt.

In a certain proportion of cases during the vibratory stage a tingling is felt in some portion of the body—the part is 'asleep.' Sometimes it is felt in one arm or in the side of the tongue, or on the side of the face, and it is on the same side as that on which the glimmering in the eye begins. Sometimes the hearing, speech, or memory is affected.

The age at which the attacks generally commence is from twelve to twenty-five. Females are more liable to them than males. After a certain period, with advancing age the attacks, as a rule, are less easily developed, and become much less frequent. They cease generally after fifty or sixty, and in women not uncommonly at the change of life.

PATHOLOGY.—Considerable diversity of opinion exists as to the nature of megrim. Formerly it was regarded as being dependent upon gastric or

hepatic derangement—a view, however, which now finds few supporters. Some pathologists hold it to be a form of neuralgia; but though it has a great resemblance to neuralgia, it ‘causes much greater disturbance of the sensorium, it spreads much more generally over the head, and is not infrequently accompanied by nausea and vomiting. After the attack there may be an intermission of weeks or months, and the attack itself runs a more uniform or continuous course’ (Lebert). The view which the writer has advanced is that the affection is to be referred to the sympathetic nervous system. If by fatigue, anxiety, or other depressing cause, the general tone of the body be lowered, and with it the regulating or inhibitory power of the cerebro-spinal over the sympathetic nervous system impaired, then uncontrolled action or excitement of one or more portions of the latter takes place, causing contraction of the blood-vessels under the influence of the affected portions, and so producing the disorders of sensation which precede the headache; this excitement is followed by exhaustion or paralysis of the sympathetic, and is associated (just as would be the case after section of the nerve) with dilatation of the vessels, and with headache. Edward Living, in his classical and exhaustive work on megrim, combats this view, and maintains that the phenomena are those of ‘a nerve-storm traversing more or less of the sensory tract from the optic thalami to the ganglia of the vagus, or else radiating in the same tract from a focus in the neighbourhood of the quadrigeminal bodies.’

TREATMENT.—By careful management very great relief can be afforded to the sufferers from this malady, not only by diminishing the intensity of the attacks, but also by considerably lengthening the intervals between them. We may consider separately the remedial measures to be employed (1) during the intervals between the attacks; (2) during the premonitory stage, or stage of disordered sensation; and (3) during the stage of headache.

1. *During the intervals between the attacks.*—It is to the treatment during this period that the greatest consideration must be given. The cause, if possible, must be discovered, and in a very large majority of cases careful inquiry will reveal the fact that a distinct cause does exist. Overwork, prolonged anxiety, over-fatigue, disappointed hopes or affections, sexual irregularities, defective eyesight, and impoverished nutrition of the body, are among the chief causes; and while these are in operation medicine will prove of little avail. Remove the cause, and then endeavour to brace up the bodily and nervous systems. The chief remedies for this purpose are the vegetable bitters, iron, strychnine, and cod-liver oil. But the success following their use very much depends upon the way in which they are administered. For a day or two after a headache the stomach and bowels may possibly be disordered, and not in a fit state to tolerate iron or cod-liver oil. This condition must be corrected, and for this purpose the simple vegetable bitters, such as gentian with small doses of henbane and some aromatic, may be of service; and if necessary one or two grains of blue pill, with four or five of compound rhubarb pill, may be given at night; but strong purgation must be avoided. Iron may then be given, either in the form of the ammonio-citrate alone, or combined with two or three grains of iodide of potassium; and according to circumstances fifteen or twenty minims of tincture of henbane, or

twenty or thirty minims of aromatic spirit of ammonia, may be added to each dose. Or the iron may be given in the form of the *Mistura Ferri Composita* of the *Pharmacopœia*; the mixture answering better, however, in some cases, without the myrrh. Strychnine is, in the writer's opinion, a very important remedial agent in many forms of this disorder, and may be given with the remedies previously mentioned in the form of *Liquor Strychninæ Hydrochloratis* or *Tinctura Nucis Vomicae*, or may be combined with infusion of quassia or calumba. Where iron is contra-indicated from any cause, or when it is not readily borne, the administration of nux vomica with quassia has seemed to act beneficially. In females with a distinct hysterical temperament nux vomica does not answer so well, and better results will be obtained by giving the vegetable bitters with ten-grain doses of bromide of potassium, and fifteen or twenty of tincture of henbane, twice or three times a day. As a rule, however, the bromide is of more use administered during the headache than in the intervals. Cod-liver oil often acts beneficially, especially when there is much nervous exhaustion. It may be given once a day immediately after breakfast, beginning with a small teaspoonful, and gradually increasing the quantity to a tablespoonful, but not beyond, unless in exceptional cases. If the bowels are constipated, five grains or so of the socotrine-aloes pill may be given at night; or if the constipation be habitual, five grains of the aloes-and-iron pill, given twice a day before meals, will generally induce greater regularity in the action of the bowels.

In some individuals megrim is associated with a strongly marked uric-acid diathesis, as shown by the fact that preceding or succeeding an attack the urine is strongly acid and loaded with lithates. In these cases fifteen or twenty grains of salicylic acid, or salicylate of sodium, twice a day, in conjunction with other remedies, to correct or neutralise the uric-acid formation, will often be of signal service.

Other remedies have been recommended, and are sometimes of service, especially arsenic and quinine.

In persons of feeble bodily power, rest is of the greatest importance, and it is often advisable that such patients should remain in bed at least twelve hours out of the twenty-four, and take their breakfast an hour and a half or two hours before rising in the morning. Whenever the headaches recur frequently, this rule should be enforced. In cases where borne, a tumblerful of new milk, to which two teaspoonfuls of brandy, rum, or whisky have been added, may be taken with advantage before breakfast, directly on waking in the morning.

The diet should be liberal; the food plain and easily digestible; and two or three glasses *per diem* of wine, beer, or porter may generally be taken with benefit, according to the habits of the patient. The more exercise the patient can take in the open air, without fatigue, the better.

2. *During the premonitory stage, or stage of disturbed sensation.*—In the forms attended by disturbance of vision, the longer this lasts the greater will be the headache, and we must endeavour therefore to shorten this stage as much as possible. Directly the glimmering appears the patient should lie down, with the head low; and if the glimmering be on the right or left of the field of vision, he should lie on the *opposite* side. Let him take at once some alcoholic stimulant, a glass of sherry, a tablespoonful of brandy diluted, or a glass of champagne. If alcoholic stimulants be objected to, or

if it be not advisable to recommend them, then a teaspoonful of sal volatile in water may be prescribed instead. If the patient be chilly, or his feet cold, the couch should be drawn near the fire, and a hot bottle applied to the feet. By these means the heart is enabled to drive the blood with greater force to the brain, and the duration of the vibratory movement is thereby materially lessened. After the glimmering has passed off, the patient should lie still for a time, so that it may not return. This injunction will only be necessary when the headache is slight; if it be severe, attended with much nausea or vomiting, the patient will be little disposed, or little able, to leave the recumbent position.

If, instead of the disturbance of vision preceding the headache, there be a feeling of depression or irritability, fidgets, and similar phenomena, the administration of such cerebro-spinal stimulants as henbane, valerian, asafetida, spirit of chloroform, or ether, will often cut short the attack. Fifteen or twenty drops of the tincture of henbane, with the same quantity of spirit of chloroform, will soothe the nervous irritability in the slighter forms, and may be repeated in three or four hours if necessary. If there be great mental depression, then valerian or asafetida should be tried. Half a drachm to a drachm of the ammoniated tincture of valerian, or the same quantity of the fetid spirit of ammonia, may be given. Sometimes Indian hemp is very useful, a quarter to half a grain of the extract in a pill, or five to ten drops of the tincture on a lump of sugar. As a rule, in such cases as these, alcoholic stimulants are not advisable at this stage. A small quantity will cause flushing, heaviness, and slight confusion of thought, without relieving the depression; and though the severe headache may be averted, alcoholic stimulants do not answer so well as the remedies previously mentioned.

3. *During the stage of headache.*—If the headache be slight, and the patient soon able to sit up, there is little to be done. A cup of coffee or tea, cheerful conversation, a walk, drive, or ride, may often help to remove the pain. If, however, the symptoms be severe, then the administration of further remedies is called for. The patient should keep perfectly still and quiet, with the room darkened; for every sound or sight causes pain, and the slightest movement is sufficient to produce gastric uneasiness. Sometimes free evacuation of the contents of the stomach, especially if it contain undigested food, is followed by relief; but, as a rule, it is better to try to relieve and check the vomiting. Iced soda-water, with or without two or three drops of diluted hydrocyanic acid or spirit of chloroform; cold tea; or the effervescing citrate of potassium with diluted hydrocyanic acid, may often afford marked relief. The headache may be lessened by applying cloths dipped in cold water or evaporating lotions to the head. If the extremities be cold, and the headache severe, a warm stimulating foot-bath can be tried, as soon as the nausea will allow the patient to sit up. If the attacks occur in the early part of the day, as soon as the pain has subsided it is generally better for the patient to sit up or move about, or even to take exercise in the open air. During the attack the appetite is diminished, even the idea of taking food provoking disgust. Still, after the nausea has passed away, a cup of soup, or some easily digested food, will often have a good effect in equalising the cerebral circulation, and in relieving the headache.

If the headache be severe, bromide of potassium is a remedy which will often prove of great service. It may be given in doses of fifteen or twenty grains, with fifteen or twenty minims of tincture of henbane, and to these may be added thirty or forty minims of the aromatic spirit of ammonia, in some cases with advantage. If necessary, the dose may be repeated after an interval of two hours or so. In some cases phenacetin or phenazone may be given with benefit in doses of seven to fifteen grains, with thirty minims of sal volatile, or acetanilide in five-grain doses, and repeated in an hour if necessary. In other cases, often of a gouty character, chloride of ammonium in doses of fifteen grains produces marked relief, and may be sometimes advantageously combined with spirit of chloroform and compound tincture of lavender. Guarana powder is a remedy which is used, often with happy results. The sick-headaches which it seems to relieve are those in which distinct premonitory symptoms usher in the attack, and particularly those preceded by disturbance of vision. It may be given in such cases in doses of fifteen grains, with the same quantity of sugar, and repeated in from half an hour to two hours. In those individuals, however, in whom the headache is developed suddenly, where the attacks come on without any or with very indefinite premonitory symptoms, guarana appears to have little effect.

As a rule, the use of purgatives in this stage is decidedly objectionable, but occasionally a saline purgative, at the commencement of an attack is indicated, and is of service.

PETER W. LATHAM.

MEINBERG, in Lippe-Detmold, in Germany.—Mixed sulphurous saline and chalybeate waters, and mud-baths. See MINERAL WATERS.

MELÆNA (μέλας, black).—SYNON.: *Dysenteria Splenica*; Fr. *Melèna*; Ger. *Schwärze Ruhr*.

This term is used to denote black tar-like evacuations that are passed from the bowel. The colour and appearance are due to *altered* blood, and the expression is not properly applicable to simple hæmorrhage from the alimentary canal, when blood of a normal appearance is voided.

In order that the blood should have undergone the change which produces the characteristic evacuations, it must have been effused high up in the canal, and in some quantity, as well as retained for some time in the bowel. When hæmorrhage takes place in the lower part of the small intestine, or in the colon or rectum, the blood is passed in a scarcely altered state, or at most renders the feces dark, without producing the black viscid motions now referred to.

Blood that is passed into the stomach, or the upper part of the small intestine, is decomposed by the various secretions and intestinal contents with which it comes into contact, and either wholly or in part is finally discharged from the rectum as sulphide of iron. The tar-like consistency is very characteristic and is probably due to the admixture of mucus with the other products of the decomposed blood. Blood derived from the stomach is less likely to be mixed with ordinary fecal matter than when derived from the intestine, as in the former case the cause of the hæmorrhage generally necessitates abstinence from food. The feces may be blackened by iron, bismuth, and other agents, taken

as drugs, but they do not produce the viscid matter like semi-digested blood.

A form of melæna, with or without hæmatemesis, has been occasionally noticed in infants within a day or two after birth. The cause is obscure, but is probably associated in some way with the disturbance of the circulation determined by the ligation of the umbilical cord. Sometimes clean-punched ulcers have been found in the stomach or duodenum in such cases, but oftener there are no indications to be seen *post mortem*. The condition, which is very fatal, is probably allied to other hæmorrhagic states met with in the new-born, such as purpura.

Melæna is the mere expression of a condition brought about by many causes, and these have to be sought for and treated. See HÆMATEMESIS; INTERSTINES, Hæmorrhage from; and STOOLS.

W. H. ALLCHIN.

MELANÆMIA (μέλας, black; and αἷμα, the blood).—See BLOOD, Morbid Conditions of, p. 161.

MELANCHOLIA (μέλας, black; and χολή, bile).
SYNON.: Fr. *Lybénie*; *Mélanholie*; Ger. *Schwermuth*; *Melancholie*.

This name is now usually applied to a form of insanity characterised by great mental depression. The sufferer in this disorder feels his whole existence, mental and bodily, overwhelmed and oppressed by gloom, anxiety, and foreboding. At first it may be only a feeling which takes no definite shape, and there may be no delusions. Sometimes, though rarely, there are none throughout; the morbid feeling constitutes the disorder, which in this form has been called *simple melancholia*. Its access is almost always gradual, and though we may attribute it to grief, overwork, or worry, it often happens that no mental or moral cause can be found, and we are obliged to set it down to inherited predisposition, to some debilitating illness, declining strength, or advancing age. Some are aware that there is no real ground for their sorrow and sadness, and are able to look on it as an illness; others feel that there must be some real cause for the despondency, that something terrible is impending, though they know not what. The majority can argue and converse rationally on subjects unconnected with their feeling of misery.

The bodily health, even at first it appears good, soon participates in the disturbance. Arterial pressure is high, the digestion disordered, the urine loaded with lithates, the skin dry, the bowels constipated, the pulse slow rather than quick, the conjunctiva dull and yellow. The patient will complain of various uneasy feelings in the præcordial or epigastric region, and this, with the state of the excretions, will confirm the notion, so prevalent among many, that the whole mischief is in the liver. Such simple depression may continue for a longer or shorter space of time. It may pass away suddenly or gradually, or the individual will grow worse in one of two ways. The depression becomes greater, and delusions of various kinds present themselves; or it is replaced by the excitement of mania.

Melancholia with delusions is far more common than *simple melancholia*, and is that which most frequently we are called upon to treat. The patient feels utterly changed, which he attributes to various causes, and deduces various results from his condition. He has all manner of diseases—syphilis, leprosy, lice; his stomach is gone, and therefore he

cannot eat. He cannot attend to business, and therefore is ruined. He is so wretched that he must have committed sins unpardonable in this world or the next. The bodily symptoms, like the mental, are aggravated. Sleep is absent or scanty; and there is rapid wasting. The bowels are loaded and resist strong purgatives; the tongue is white and furred; the breath offensive. The patients are for the most part elderly; climacteric insanity is almost always melancholia. Of 338 melancholic patients admitted into St. Luke's Hospital only nine were below the age of twenty.

It cannot be too strongly impressed upon medical men that all melancholic patients, even those whose disorder seems simple and slight, are, especially in the early stage, very apt to commit suicide. We read accounts almost daily in the newspapers of suicides committed by this class of persons; and most lamentable they are, for it is a class which above all others is amenable to treatment.

An asylum is not absolutely requisite for such, if their means allow of proper companions, house, and exercise. They must not be left alone by night or day; must not be left to attendants only; and must have some amusement or diversion. If all this cannot be provided, to an asylum they must go; for if they are resolutely and constantly bent on suicide, it is most difficult to guard against it in an ordinary house.

Whether they are sent to an asylum or not, it is found to be almost invariably necessary to remove them from home. We may think the case a slight one, and hope that amusement and cessation from work, with medical treatment and good living, will remove the depression. Again and again we are disappointed. The sight of home and home scenes, of family and friends, and the contrast between past happiness and present gloom, perpetuate the melancholy and prevent its dispersion. After valuable time is lost, we are compelled to send away the patient to an asylum or quasi-asylum.

PROGNOSIS.—The prognosis in cases of melancholia is favourable, and patients get well in great numbers, even at an advanced age. It is also important to remember that recovery may take place from this form of insanity after considerable periods of time. The writer has recorded cases of melancholia in which recovery took place after five, six, seven, and nine years respectively. In dealing with property it is often necessary to consider the question of probable recovery, and it is well to keep in view the chance of it here, although in perhaps every other form of insanity recovery after such periods would be out of the question.

TREATMENT.—On examination of a melancholic patient, it is generally found that there has been a considerable loss of flesh. This may be due to the mental care and sorrow, but is often caused by an insufficient quantity of food, which has been scanty, either because all appetite has been lost owing to the prevailing wretchedness, or because, from various delusions, there has been an unwillingness to take food. Moreover, there is almost always considerable disorder of the digestive apparatus, the result and not the cause of the depressed nervous condition. The first thing to be done is to correct this disorder; and then to restore the defective nutrition of the brain.

One symptom is obstinate constipation. It may be necessary in the first instance to relieve the

loaded and obstructed bowel by means of turpentine enemata; after which it will be of advantage to give a daily dinner pill of the extracts of aloes and nux vomica, or a daily teaspoonful of castor-oil, following it up if necessary by an enema, but ensuring an action every, or every other, day, and so habituating the bowels to act. Many melancholic patients, especially women, will be found to be persons who have been accustomed to go for long periods without any action of the bowels, or who never had relief without medicine. Food must be given to this class of patients in large quantities. It constantly happens that it is withheld from them under the impression that their malady is essentially dyspepsia, and that the stomach must not be called upon for much exertion. Many, as has been said, refuse it for one reason or other. In either case the melancholia increases, and the patient gets thinner and weaker. Food must be given with no sparing hand—not merely beef-tea and invalid diet, but solid food—bread, meat, and eggs, with a liberal allowance of wine or malt liquor. In some cases artificially digested food may be useful. Some require forcible feeding, and this can hardly be carried out except in an asylum; but many by coaxing or threats will take what is given to them with a spoon, and they must be fed frequently till they will take the meals of their own accord. Under this augmented diet the tongue will become clean, the bowels will act without physic, and the patient's appearance will soon testify to the efficacy of the treatment. *See* FORCIBLE FEEDING.

Sleep, though not entirely absent, will be in defect owing to the high arterial pressure. To lower this, erythrol tetranitrate in half-grain doses has been recommended, and is said to act like a charm, in many cases reducing the pressure and inducing sleep. In some, however, it fails, and hypnotics are necessary. In the same way opium fails in some patients, though in a large number of melancholics it is most valuable, not merely procuring sleep, but alleviating the feeling of wretchedness. It may be given either by the mouth or by subcutaneous injection of morphine. It is of importance that we do not give a preparation which shall cause sickness or constipation; the ordinary preparations of morphine, the acetate and hydrochloride, are apt to do this if given in full doses, and it is better to substitute Dover's powder, Battley's solution, or solid opium if we can be sure that pills will be swallowed. Chloral hydrate will procure sleep here as in other cases, and may be combined with opium to bring about more speedy action of the latter, but has not such a lasting influence on the malady; when its sleep-producing effect has passed away the patient does not feel any benefit from the medicine. Paraldehyde, also, is often useful. The bromides should on no account be given. They will increase the emaciation and depression. When the secretions have been corrected, and digestion is re-established, tonics may be useful, especially the preparations of iron and arsenic.

VARIETIES.—Two varieties may be mentioned.

1. **Acute Melancholia.**—Although the prognosis in simple melancholia, and that which may be called sub-acute, is so favourable, there is an advanced stage which truly merits the name of *acute*, or *acute delirious melancholia*, and generally terminates fatally. The patients are not silent, gloomy, and depressed, but panic-stricken; and in

violent frenzy and terror they try to escape from those about them, tear off their clothes, gouge out their eyes, and injure themselves in every way. They will not lie on a bed unless forced to do so, but will prefer the floor or incessantly pace the room. Food they resist with all their power, thinking that it is poisoned or that they will be punished for taking it. Such patients must be fed by force, and fed early, but it often happens that our feeding here is of no avail, and they sink from the exhaustion of this acute disorder. For it is constantly found in those who are already broken and debilitated in health, and is but the last stage of a series of disorders. The incessant agitation, violence, and sleeplessness produce rapid wasting and sinking; the food administered is not assimilated, and fails to restore the wasted force. This form of melancholia runs a rapid course, but nevertheless tends to recovery in some cases. We may administer the erythrol tetranitrate, opium, or paraldehyde. Cod-liver oil may be added to the food. Warmth and stimulants are demanded; and clothes must be kept on by means of a strong suit which cannot be removed by the patient.

2. **Mélancolie avec Stupeur (Fr.)**—**SYNON.**: Ger. *Schweremuth mit Stumpfsinn*.—A more extreme form of melancholia is thus named, where the patient sits or stands, speechless and motionless, and requires to be fed, washed, and dressed. Though such a one will not speak or do anything for himself, he may be watching every opportunity of committing suicide, and he will even strenuously refuse food with the same motive. The vital powers in these persons are greatly depressed, and they require an exceptional amount of nutritious food and stimulant. This form of melancholia has been confounded by some with that variety of insanity termed 'acute dementia' (*see* DEMENTIA); but the latter occurs only in young people, whereas melancholia as a rule occurs in persons of more advanced years; and the early symptoms are quite different, acute dementia coming on rapidly, and without the depression and gloomy delusions which mark the other complaint. *See* MENTAL STUPOR, p. 766.

G. F. BLANDFORD.

MELANIN.—*See* BLOOD, Morbid Conditions of (p. 161); PIGMENTATION; and URINE, Morbid Conditions of.

MELANOMA (μέλας, black).—Any morbid growth in which the presence of dark pigment is a leading character. *See* TUMOURS.

MELANOPATHIA (μέλας, black; and πάθος, a disease).—An excess of black pigment in the skin, due to abnormal function of the rete mucosum. Melanopathia is rarely general, more frequently partial. In certain instances, as in the 'bronzed skin' of Addison's disease, it is associated with anæmia. *See* PIGMENTARY DISEASES OF THE SKIN.

MELANURIA.—*See* URINE, Morbid Conditions of.

MELASMA (μέλας, black).—A term usually applied to excess of pigment in the skin, from abnormal function of the rete mucosum. *See* PIGMENTARY DISEASES OF THE SKIN.

MELLITURIA (*mellitus*, honeyed; and οὔρον, urine).—A synonym for saccharine urine. *See* DIABETES MELLITUS.

MEMBRANA TYMPANI, Diseases of. —
See EAR, Diseases of.

MEMBRANES OF BRAIN AND CORD, Diseases of. — See MENINGES, CEREBRAL, Diseases of; MENINGES, SPINAL, Diseases of.

MENIÈRE'S DISEASE. — See VERTIGO.

MENINGES, Diseases of. — For purposes of convenience these will be grouped under the heading of (1) *Cerebral Meninges*, and (2) *Spinal Meninges*, although in some instances the cerebral and spinal meninges may be simultaneously affected, as in epidemic cerebro-spinal meningitis and occasionally in a sporadic form of cerebro-spinal meningitis.

The following morbid conditions will be considered under this heading:

I. Cerebral Meninges:

- (1) Simple Idiopathic Meningitis, p. 977.
- (2) Traumatic Meningitis, p. 979.
- (3) Tubercular Meningitis, p. 979.
- (4) Posterior Basic Meningitis, p. 983.
- (5) Pachymeningitis Hæmorrhagica, p. 985.
- (6) Hæmorrhage, p. 986.

II. Spinal Meninges:

- (7) Traumatic and Secondary Meningitis, p. 988.
- (8) Idiopathic and Tubercular Meningitis, p. 988.
- (9) Hæmorrhage, p. 991.

Syphilitic affections of the cerebral meninges are described in the article on BRAIN, Syphilis of; new-growths, in BRAIN, Tumours of; and septic inflammations, in BRAIN and MENINGES, Septic Diseases of. See also INSANITY, Pathology of; and GENERAL PARALYSIS OF THE INSANE.

Tumours and local affections of the spinal meninges are discussed in the sections on Diseases of the Spinal Cord. See also MENINGITIS, Epidemic Cerebro-spinal; and MONSTROSITIES and MALFORMATIONS.

I. Simple Idiopathic Meningitis. — SYNON.: Simple Idiopathic Cerebral Leptomeningitis; *Leptomeningitis Infantum* (in part); Fr. *Méningite Simple*; Ger. *Acute Hirnhautentzündung*.

DEFINITION. — A simple non-tubercular inflammation of the cerebral pia mater, which may be either limited to the convexity, general, or confined to the base of the brain. It is associated with very variable symptoms in different cases; and is probably caused in many different ways.

ÆTIOLOGY AND PATHOLOGY. — Our knowledge of the ætiology and pathology of acute idiopathic cerebral meningitis has of late years become more definite.

It appears that sex exercises an influence in the production of idiopathic meningitis, and that the disease occurs much more frequently in males than in females. In regard to age, it is met with almost as frequently in individuals from ten to twenty as in those below the tenth year. In individuals over twenty the disease is much more rare.

Meningitis is apt to occur during, or as a sequel of, many acute febrile diseases, such as pneumonia, measles, scarlet fever, small-pox, and rheumatic fever. Such associations are, of course, rare, but much less so with pneumonia than with either of the other diseases named. It may also complicate erysipelas of the head and face; or it may occur as an accompaniment of ulcerative endocarditis or pyæmic processes, owing to these conditions leading to minute embolisms of the vessels of the pia mater.

In all these cases it is supposed to have an infective origin, and is associated with the presence of different micro-organisms.

Sometimes it is met with in extremely cachectic subjects, who have not previously been suffering from any acute disease. It has been known to follow prolonged exposure to the sun; to ensue after the occurrence of severe moral perturbations; and likewise to follow a shock or blow, even when this has not been complicated with an external wound, or with a fracture of one of the bones of the skull.

In other cases, also, a meningitis really secondary may appear to be primary and idiopathic, as when (a) it extends from some focus of syphilitic disease of the meninges, or (b) when it occurs as a sequel of some unrecognised chronic inflammation involving the middle ear and portions of the temporal bone.

ANATOMICAL CHARACTERS. — Simple idiopathic inflammation of the cerebral meninges is a condition which varies much in severity in different cases. In its earliest or initial stage, nothing more than a minute and more or less uniform injection of small vessels and capillaries in certain regions of the cortex may be met with. But later on, definite products of inflammation are to be seen; these are for the most part situated beneath the arachnoid, in the meshes of the pia mater. They consist, according to the stage of the morbid process, either of a gelatinous white or yellow lymph-like matter, of actual pus, or of more coherent yellow lymph in the form of membranous layers. In regard to the area involved considerable differences also exist. The inflammation (1) may be limited to the convexity and to the lateral regions of both hemispheres; (2) it may be general, that is, involve the parts above mentioned, and also the base; or (3) it may be limited to the basal regions of the brain. In both the latter cases the ventricles are apt to contain fluid, and the central parts of the brain to be softened, as they are in tubercular meningitis, which also affects the base in a special manner.

Of these varieties as to seat, the first, in which the convexity is involved, is decidedly the most typical, and in this respect simple idiopathic meningitis contrasts in a salient manner with tubercular meningitis, in which the tendency is no less marked to implicate the base of the brain. In the second variety, the inflammation beginning above probably extends to the base by mere continuity, in cases where the condition of the patient, or the intensity of the inflammatory process itself, favours its spread from the original site; or, in certain cases, the inflammation may be from the first general in seat.

In regard to the third variety, doubtless many of such cases have been instances of what we now know as 'posterior basic meningitis.' In these cases the basal inflammation may co-exist with, or be an extension upwards from the spinal meninges of an inflammation beginning there—a case, in fact, of cerebro-spinal meningitis of sporadic type. On the other hand, we may have to do with one of those cases of tubercular meningitis where the general disease manifests itself on the side of the brain first, and in which the patient dies before the local process is at all fully developed. In such a case the inflammation may be really of the tubercular variety, and yet to superficial observation not recognisable as such.

In all these cases the inflammation may be limited to the meninges themselves, or the surface of the

brain may also be manifestly involved in the inflammatory process, so that we then have to do with a *meningo-encephalitis* of varying seat and extent.

SYMPTOMS.—In no disease is the symptomatology more various than it is in acute meningitis—a fact partly due to the varying intensity of the inflammatory process, partly dependent upon the process being localised or more general, and partly according as there is or is not the co-existence of dropsy of the ventricles with inflammation of their walls. Independently of these causes of variation there is the fact that the symptoms of the meningeal inflammation are, in the numerous cases in which it occurs as a secondary affection, apt to be complicated and more or less overshadowed by those of the acute disease to which it owes its origin. Sometimes the disease is almost latent, accompanied only by slight symptoms, merging into stupor and coma a day or two before death. Or the symptoms may be marked and quite tragic in their severity; ushered in either by frightful pains in the head, by well-marked delirium, or by convulsions; subsiding eventually into a condition of stupor or coma; and followed by death within eight or ten days, though this may be delayed till the expiration of three weeks or a month. Recovery, which sometimes occurs, must be regarded as a rare event.

Inasmuch as it is not practicable, within the limits of this article, to give a detailed account of the various groupings of symptoms that may be met with in different cases, we must confine ourselves to an enumeration of the symptoms themselves, most apt to occur (1) in the early stages of the disease, and (2) in its later phases.

(1) Cephalalgia of an intense character, either general or localised in some particular region or regions of the head, may be complained of again and again where the patient is old enough, or, if he be too young, is indicated by cries, by application of the hands to the head, or by other signs. Sometimes, however, this symptom may be almost absent, or it may come on at a later date. Delirium, occasionally furious, at other times more quiet and of a simply loquacious type, is another symptom; or there may be extreme restlessness. Mere insomnia, too, sometimes exists from the commencement; while at other times a semi-comatose condition, gradually deepening into actual coma, may exist from the first, especially in children, or it may succeed a transitory delirious condition. Nausea and vomiting, and also convulsions, either local or general, may be met with in the early stages of the disease, and sometimes as initial symptoms. With them will go general pyrexia and sometimes rigors; also heat of head, rapid pulse, a furred and often thickly coated tongue, constipation, perhaps some intolerance of light and of loud sounds, together with an easily obtainable *tache cérébrale*, and often some amount of hyperæsthesia of the skin.

(2) As later symptoms, we may have localised convulsions or spasms, often of the tonic order, affecting perhaps the head and neck (which, especially when the posterior part of the base is involved, are frequently drawn backwards) or one or both arms; or a condition of trismus may exist. The eyes, too, are sometimes drawn upwards. The pupils may be at first contracted, or, if not, they may be of medium size, unequal and insensitive;

while later on they are most frequently widely dilated and insensitive. The conjunctivæ are often injected. Paralysis of one arm, or sometimes of an arm and a leg, may occur. The condition known as 'Kernig's sign' may also exist, but it is occasional and fitful only in its presence, and the patient may not be in a condition to permit of its being looked for. It consists in the impossibility of completely extending the leg upon the thigh when the patient is in the sitting position. The sensibility of the skin may be either exalted or deadened. The abdomen is often hollow and boat-shaped. The tongue becomes thickly coated, or dry and brown. Difficulty of deglutition is frequently well marked towards the end; and there is incontinence of feces and urine as soon as the stupor becomes marked. Sometimes the pulse is unnaturally slow and infrequent from the first; at other times, and especially towards the end, it is very frequent and irregular. The respiration, too, becomes much disturbed, being often sighing and of very irregular rhythm, tending to become stertorous at last. The temperature is frequently high, but pursues a markedly irregular course. Remissions of the pyrexial condition may take place from time to time. The skin is generally hot and dry, though occasionally there may be copious sweats. Stupor and coma almost invariably occur at the last, if not present at an earlier stage.

PROGNOSIS.—A large number of deaths take place within the first week of acute meningitis; a much smaller number survive till the end of the second week; fewer still reach the end of the third; and only a very few survive to the fourth week. It is difficult to say what the percentage of recoveries may be, but probably less than ten would survive out of a hundred cases of acute idiopathic cerebral meningitis.

DIAGNOSIS.—The diagnosis of idiopathic meningitis involves considerations very similar to those arising in the diagnosis of tubercular meningitis, and need not therefore now be discussed. *See* MENINGES, CEREBRAL, Inflammation of, Tubercular.

The diagnosis of simple from tubercular meningitis must oftentimes be a matter of extreme difficulty. Whether the condition of the blood, as recognised by the aid of the microscope, is the same in simple meningitis as it is in tubercular meningitis the writer is unable to say. Should it not be so, some help might be obtained in this direction. The conditions under which the disease seems to develop may throw some light upon the problem. In regard to special symptoms, the possible range is so great in each variety that it becomes difficult to fix upon any that are positively distinctive of the one or of the other. Delirium is, however, rarely so violent in tubercular as it may be in simple meningitis. Retraction of the head is also not so frequent in the tubercular variety. On the other hand, the temperature much more frequently rises over 101° F. in simple than it does in tubercular meningitis. Finally, it must be borne in mind that the former is an extremely rare disease, the latter unfortunately only too common; and that while in tubercular meningitis the two sexes fall victims with about equal frequency, in the simple variety two out of three are likely to be males.

TREATMENT.—In the early stages of acute simple meningitis aperients may be freely administered. A leech or two might be applied to the

temples, in cases where pain is greatly complained of; or under the same conditions the head may be shaved and an ice-bag or Leiter's tubes may be applied, should such measures not be deemed useless on account of the extreme restlessness of the patient. The writer believes that little or nothing is at present to be expected from drug-treatment towards the cure of this disease, although some alleviation of the more distressing symptoms may at times be brought about by special attention to them. The patient requires to be carefully fed, and assiduously nursed and kept quiet throughout, in the hope that the end may be favourable.

H. CHARLTON BASTIAN.

2. Traumatic Meningitis.—Suppuration of the meninges following injuries to the head is always caused by the introduction of pyogenic micro-organisms, and owing to the intimate relationship of the pia mater and arachnoid to the brain, we always find that they are all three involved in the process. Septic inflammation of the pia mater and arachnoid are considered in the article on BRAIN AND MENINGES, Septic Diseases of. The relation of the *dura mater* to the brain is very different from that of the other two membranes. It is intimately connected with the skull, in all probability acting as regards the cranium like the periosteum of long bones. The thin connective-tissue layer on the outer surface of the cranium termed the pericranium can scarcely be looked upon as a periosteum. It has no osteogenetic function, and its vessels supply but few branches to the bones of the skull. The meningeal arteries are mainly concerned in the blood-supply of the skull, only a very small proportion of the blood passing through them being required for the nourishment of the *dura mater*.

In its behaviour to septic organisms the *dura mater* differs markedly from the other membranes. It acts as a very efficient barrier in preventing septic conditions of the skull-bones from reaching the brain. In cases of compound fractures, whether depressed or not, very free suppuration may take place, and, so long as there is free drainage from the surface of the *dura mater* through the scalp-wound, septic inflammation rarely spreads inwards, but if the *dura mater* is wounded there is at once enormous risk of septic inflammation of the brain and its meninges proper, i.e. leptomeningitis. Although inflammation of the *dura mater* sufficient to cause symptoms, and therefore to be of clinical rather than pathological interest, is nearly always septic in origin, yet there are a few cases in which the inflammatory and reparative processes that may follow injury are of sufficient extent to cause symptoms, e.g. in every simple fracture of the skull there is probably some injury to the *dura mater* at the line of fracture, and some blood is poured out from the small ruptured vessels. The ordinary inflammatory reaction with oedema may cause slight cerebral compression for a few days; again in healing there may be formed an amount of fibrous tissue sufficient to press upon the subjacent brain and, if the motor area be involved, to cause traumatic epilepsy. After injuries in which a large effusion of blood forms between the *dura mater* and the bone blood-cysts may develop, and these together with the thickening of the *dura mater* may cause symptoms of cerebral irritation or compression. The chief affections of the *dura*

mater, however, are septic processes spreading from the bone. In most cases there is a wound of the scalp and there may be fracture of the skull. In the former case the septic osteitis spreads inwards to the *dura mater*. In the latter cases there may be a direct entrance of pyogenic germs to the *dura mater*. This process takes some time to lead to the formation of pus, and the wound of the scalp is very often healed by the time the abscess reveals its presence. From the inflamed bone serous exudation may spread into the scalp and cause a localised oedematous swelling first described by Percival Pott, and termed by him the 'puffy tumour.' In some cases this septic pachymeningitis or sub-cranial abscess may form without any apparent wound of the scalp. No doubt sometimes the septic material enters by small abrasions which are overlooked, and at other times the deeper layers of the tissues of the scalp are crushed, and any organisms lying in the hair-follicles or sebaceous glands may readily gain entrance into the tissue and spread to the bone, bruised by the violence of the injury. In either case the diploic veins become thrombosed. As soon as the organisms reach the bone a septic osteitis commences which results in the formation of an abscess on the outer surface of the *dura mater* and a serous exudation in the adjacent region of the scalp—*puffy tumour*. If the tension existing between the bone and *dura mater* is not relieved by surgical means the septic process will extend to the brain. The resistance of the *dura mater* is proved by the long time that the septic inflammation may exist before spreading to the underlying brain. If the *dura mater* has been wounded at the time of injury it may become adherent to the subjacent membrane and permit the extension of organisms to the brain and the formation of a sub-dural abscess.

The symptoms and treatment of these conditions are the same as those in cerebral abscess and septic leptomeningitis to which the reader is referred. See BRAIN AND MENINGES, Septic Inflammation of.

HENRY PERCY DEAN.

3. Tubercular Meningitis.—SYNON.: Granular Meningitis; Acute Hydrocephalus; *Hydrocephalus Internus*; Brain-Fever (in part); Tubercular Leptomeningitis; Fr. *Fièvre Cérébrale*; *Meningite Granuleuse*; *Meningite Tuberculeuse*; Ger. *Tuberculöse Hirnhautentzündung*.

DEFINITION.—An acute and extremely fatal febrile disease, with a predominance of head-symptoms; terminating in stupor and coma, with or without convulsions; and characterised after death by a 'granular' meningitis affecting the pia mater at the base of the brain, with the frequent accompaniment of dropsy of the lateral ventricles, and softening of their walls. The inflammation of the membranes at the base of the brain is commonly found to be associated with a more or less marked spinal meningitis.

Tubercular meningitis is not an independent affection; it constitutes one important phase of acute tuberculosis. In certain rare cases death takes place from meningitis, before the anatomical marks of the general disease have had time to develop within the chest or abdomen. More frequently, however, the manifestations of the general disease are already well developed in one or other, or in both, of these situations, at the time that they reveal themselves also on the side of the brain. In

the latter, and by far the most common class of cases, the symptoms met with will be in part those of the general affection, and in part (but in a predominant degree) those due to implication of the brain and its membranes. See TUBERCULOSIS.

ÆTIOLOGY.—The ætiology of tubercular meningitis of course resolves itself into the ætiology of the general disease, acute tuberculosis, of which it forms part.

The affection is one which occurs with special frequency in young children, between two and six years old, though it is also met with in infants, in older children, in young adults, and even in persons beyond middle age. In adults it is most apt to manifest itself as an occasional complication in the course of pulmonary phthisis. In children a proclivity to the disease seems often to be inherited, so that two or more in the same family may be carried off by it. But in what proportion of cases any such proclivity exists is unknown.

ANATOMICAL CHARACTERS.—When the calvaria is removed, the dura mater is found to be tightly stretched over the brain; unless, as the writer has seen, the subject be an elderly person, in whom some amount of senile wasting had previously occurred. On stripping back this membrane, the arachnoid presents a dull appearance, and it is slightly sticky when touched. The convolutions of the vertex and lateral regions of the brain are mostly seen to be more or less flattened from pressure, and the sulci are correspondingly indistinct. No lymph may be seen; or at most a small quantity, in the lower parietal regions, along some of the branches of the middle cerebral arteries. When the brain is removed, however, and its under surface is examined, a more or less opaque white or yellowish lymph-like matter may be seen, beneath the arachnoid, in the meshes of the pia mater, extending from the optic commissure backwards over the central portions of the base and onwards over the pons. In certain cases lymph and evidences of recent inflammation are found round the medulla, and even along the whole length of the spinal cord. More or less lymph also extends on each side into the Sylvian fissures. A minute inspection will likewise show that the tip of the temporo-sphenoidal lobe, and the orbital surface of the frontal lobe, are flecked with a number of translucent granulations, as though the parts had been sprinkled with fine sand; and on opening up the Sylvian fissure on each side, similar granulations, with others more opaque and of larger size, may be seen among the lymph in this situation. Translucent granulations also sometimes exist scattered more sparingly over the lateral aspects of the hemispheres, especially along the sides of the vessels.

Examination with the microscope shows that the granulations are composed of overgrowths of tissue-elements immediately surrounding the smaller vessels, and within their perivascular sheaths. Within and among these cellular elements the *Bacillus tuberculosis* is to be met with, though very sparingly. In these situations the tissue-overgrowths may cause a local bulging of the sheath, either all round, or merely on one side of the vessel; and when such growths become opaque from incipient fatty degeneration, they are then more easily visible as minute white specks. A close examination of the prolongations of the pia mater dipping between the convolutions, with the aid of lens or microscope, will often show minute granulations not otherwise

recognisable—and that, too, in many regions of the brain. And in cases of incipient tubercular meningitis, where the amount of lymph about the base is extremely slight, the lens or microscope may show the presence of granulations, not otherwise recognisable, in and around the lower part of the Sylvian fissures—that is, in the regions where they are most prone first to manifest themselves.

The pia mater is generally unduly adherent to the surface of the convolutions, so that it can only be removed in small shreds, and then not without tearing the superficial grey matter. This condition of things is the very opposite of what may be met with in some cases of simple meningitis affecting the vertex, in which the thickened pia mater, with all its prolongations, may sometimes be easily stripped off from the greater portion of a hemisphere in one piece.

The substance of the brain is commonly much more vascular than natural. The lateral ventricles are usually moderately dilated, containing from two to four or six ounces of not very clear serum. The veins on their surface are then engorged, and the fornix and other adjacent parts may be more or less softened, or actually diffuent. Microscopical examination of such softened tissue will reveal the presence of an abundance of fatty débris; and its specific gravity, if estimated, will be found to be diminished—both these characteristics being marks of a pathological softening which has occurred during life, and not of a softening due to mere *post-mortem* maceration. Some have erroneously supposed that such mere maceration has been adequate to produce the softening.

Sometimes the above-described changes are more fully developed in one than in the other hemisphere; and occasionally also in some parts of the brain small nodular growths of a 'tubercular' nature may be met with, varying in size from a small pea to an almond. These growths are most apt to occur in the substance of some of the cerebral convolutions, or near the surface of the cerebellum, or even, as the writer has seen, within the substance of the corpus striatum. In many such cases the small nodular tumours will be found to be in intimate relations with the vessels of the part, and, in fact, to be composed of a mere aggregate of the smaller 'granulations' more or less fused into a single mass.

PATHOLOGY.—The granulations begin to appear first in the meninges of the base under those irritative influences, whatever they may be, which lead to the development of similar grey granulations in other organs of the body. These primary changes excite a common inflammation of the membranes around, and thus entail the production of the lymph, which covers the base of the brain, and extends on either side into the Sylvian fissures. Why the grey granulations should tend to develop first, and specially about the vessels at the base of the brain, cannot at present be explained.

This inflammation of the basal meninges also extends, by direct continuity of tissue, over and around the cerebral peduncles to the velum interpositum, and to the connective tissue at the upper and anterior extremity of the middle lobe of the cerebellum. In one or other situation, and often in both, the tissues are thickened by lymph. The writer has seen the velum interpositum thick and leather-like in consistence, and the *venæ magnæ Galeni* which run through it blocked by thrombosis; and this he

believes to be an additional occasional cause of the central softening and dropsy previously referred to as component parts of the disease. In other cases, where no such thickening or thrombosis is to be detected, there is great swelling of the connective tissue, from development of lymph, opposite the termination of those great veins which return the blood from the surface of the ventricles and from the central parts of the brain—at the point, that is, where the veins of Galen empty themselves into the straight sinus.

In this way the very common association of the central ventricular changes with the basal meningitis may be accounted for, and also the occasional absence of such changes, in instances where the inflammation, apt to be set up through mere continuity of tissue, does not attain sufficient proportions to interfere with the return of blood, either through the veins of Galen, or from them into the straight sinus. Undoubtedly the mere dropsical effusion into the ventricles will also be in part due to the frequent closure of the foramen of Majendie in the fourth ventricle; such closure preventing the draining away of fluid from the lateral ventricles, and thus leading to their dilatation. It is of course possible that the central softening may also be favoured by an independent affection of the small vessels situated in the walls of the ventricles, and a development of granulations around them—though this has not hitherto been recognised. It is, however, well known that thrombosis is extremely apt to occur in those minute vessels in various parts of the brain which are enveloped by granulations—a fact that goes far to account for the extreme gravity of the symptoms in many cases of tubercular meningitis, in which naked-eye changes appear to be slight and altogether disproportionate in amount.

SYMPTOMS.—The symptoms presented in different cases of tubercular meningitis often vary very widely from one another, although among them all there is an underlying bond of similarity. The variation may be easily understood from a consideration of the fact that such symptoms form part of those pertaining to a febrile affection characterised by other local manifestations, of varying importance in different cases; and also from the fact of the differences constantly met with in the relative and absolute development of the different kinds of changes encountered within the cranium itself in this disease—especially in regard to the amount of ventricular effusion and central softening existing in conjunction with the meningeal inflammation, which again itself varies much in intensity and in regard to the area involved in different cases.

It is, therefore, usual and most convenient to enumerate the possible signs and symptoms of this disease as they occur in three stages—artificial and often ill-marked from one another as they are—namely (1) those of the *invasion-stage*; (2) those of the *developed disease*; and (3) those of its *closing phases*.

(1) *Stage of invasion.*—Among the initial symptoms of tubercular meningitis may be mentioned obstinate and recurrent vomiting, often associated with constipation; coming on frequently after a period of previous malaise; and associated with fretfulness, slight wasting, indisposition to play, and disturbed sleep. Soon after, or simultaneously, there may be more or less marked indications of cephalalgia. Young children who cannot speak are fretful and constantly cry; they often also put their

hands to their head. Such children start and cry out in their sleep. The temperature may be as yet scarcely, if at all, elevated; or there may be rigors from time to time, with temporary feverishness, recurring daily about the same hour. The child often cries out when touched, and a more or less general hyperæsthesia of the skin seems to exist.

(2) *Developed disease.*—In the second stage any feverishness that may have existed often abates. There may be less restlessness, so that the child even sleeps more than natural. The pupils are often insensitive to light, and unequal. There is frequently also some slight or perhaps marked strabismus. The pulse is apt to be much less frequent than natural (56–70 per minute perhaps), and decidedly irregular. The hypersensitiveness of skin may have disappeared, but a peculiar vaso-motor irritability exists, so that when the nail of the forefinger is drawn once across the skin of the abdomen or other part a deep red linear mark comes out slowly, and persists a long time. This so-called *tache cérébrale*, while also met with in other affections, is, as Trousseau rightly enough insisted, rarely absent in tubercular meningitis. Frequent plaintive cries may be uttered, though the child is generally more quiet and drowsy; it is apathetic also in regard to food, not asking or crying for it, but still taking it, perhaps well, whenever it is administered. Convulsions may occur during this stage, or weakness of one or more limbs may be noticed, especially where larger tubercular nodules occur in certain regions of the brain-substance. Sometimes, however, the paralysis is of a shifting and transitory nature, varying in degree or even in situation in the course of a few days.

(3) *Closing phases.*—In the closing stages of the disease the drowsiness may gradually deepen into stupor or actual coma; though in conditions short of the latter the child may still more or less frequently utter plaintive cries. The pulse, instead of being less frequent than natural, now becomes preternaturally frequent; while the respiration often assumes a slow, sighing, and markedly irregular type. The face, frequently pale and clammy, flushes at times. The head is hot, and the temperature generally raised, though often not more than to 100° F., and rarely beyond 102°, until quite to the close of the disease. The fontanelle is raised, and there may be unnatural pulsation. The eyes, when examined with the ophthalmoscope, may show evidences of grey granulations in the choroid, and perhaps some amount of optic neuritis. The pupils may be unequal, but are generally dilated and insensitive. Occasionally the writer has seen a rhythmical contraction and dilatation go on, especially on exposing them to light. In this stage, when the patient is sufficiently conscious, it may be found that sight is notably impaired or almost lost.

The patient may take the food which is given up to the last; though at other times there seems to be an actual inability to swallow it, even when it is placed in the mouth, owing to partial paralysis of the muscles of the tongue and pharynx. The abdomen is often boat-shaped and retracted; and an obstinate constipation still continues. Even in this last stage of the disease a temporary and delusive lull may take place; the child may seem to revive a little, but only too soon to lapse again into a state as bad as, or even worse than, before. Frequent and long-continued convulsive seizures are especially apt to occur during this stage of the disease; and

death may take place during or immediately after one of these attacks. At other times the end is brought about more gradually, through progressing failure in the heart's action, combined with disturbance of respiration. In the latter class of cases the temperature may gradually fall, during the last few hours before death takes place, to several degrees below the normal; though in other cases of tubercular meningitis there is a slow and steady rise of temperature up to 105° or even 106° , before the patient expires.

DIAGNOSIS.—In the early stages the diagnosis of tubercular meningitis may present extreme difficulties. We must wait, before expressing a definite opinion in one of these doubtful cases, till the patient has been seen and examined two or three times. The premonitory symptoms and those of the first stage are often far from distinctive. They may, it is true, represent the beginning of tubercular meningitis, but, on the other hand, they may also represent something less serious—for instance, a mere failure of health from various causes, complicated by dentition, by some gastro-intestinal irritation, or perhaps the commencing outbreak of some one or other of the specific fevers. Details as to the child's condition during the last two or three weeks, comprising the order of evolution of the several symptoms, may, however, throw some important light upon the real nature of the case at an early stage of the disease.

A contributory cause of the difficulties besetting the early diagnosis of tubercular meningitis is to be found in the fact that acute tuberculosis is itself extremely difficult to recognise. We cannot, therefore, readily fall back upon a diagnosis of the general condition in order to strengthen our diagnosis of tubercular meningitis. As a matter of fact, it is just the reverse. Of all the local manifestations of this disease, those within the head produce by far the most definite set of symptoms, so that we can always most safely infer the probable existence of acute tuberculosis with grey granulations throughout the body, from the presence of the developed symptoms of tubercular meningitis.

The existence of a particular habit or build of body in cases of acute tuberculosis, to such an extent as to make it possible to use the recognition of it as an aid to diagnosis in a case otherwise obscure, is practically unknown. See **TUBERCULOSIS**; and **PHTHISIS**.

The symptoms of the established disease are therefore alone distinctive, to any really trustworthy extent, of the existence of tubercular meningitis, and through it of the presence of its general underlying condition. We may have our suspicions before, but these can only transform themselves into certainties as the disease actually develops, and as it passes, moreover, into the incurable stage.

At this phase of the disease the alternative conditions to be thought of are in the main either typhoid fever on the one hand, or else some form of intracranial disease other than tubercular meningitis. Here, as in almost all cases of brain-disease, we have to look not to any one or two signs or symptoms which can be regarded as pathognomonic, but rather to the sum total of symptoms, and to the way in which they are grouped. With the possible existence of some or all of the premonitory and initial symptoms already enumerated, if the patient becomes more somnolent; if the pulse falls much below the normal in frequency, and is at the

same time irregular; if, with a condition of fever still existing, the child does not constantly crave for drink; and especially if there is also the combination of obstinate constipation and a retracted abdomen, together with an irregular and sighing form of respiration—we may feel more and more certain that we have not to do with even one of the most anomalous forms of typhoid fever associated with head-symptoms—nor, indeed, with any form of intracranial disease other than tubercular meningitis. An examination of the temperature-chart may considerably aid us in the same direction, and so also may an examination of the blood. See **SERUM-REACTION**; **BLOOD**, Morbid Conditions of (p. 157).

The writer has in many cases found distinctive alterations in the blood drawn from the finger-tip. The white corpuscles (more numerous than natural) within ten to fifteen minutes show signs of great amoeboid activity, by the development of vacuoles within them, and of numerous projections from their outer surface; among the blood-corpuscles groups of protoplasmic particles of various sizes, as well as here and there a small pigment granule or an irregular block of blackish-red pigment, are to be found. The red corpuscles form 'clumps' rather than rouleaux.

Lumbar puncture has of late years been occasionally had recourse to as an aid to diagnosis (see **LUMBAR PUNCTURE**). Tubercle-bacilli may be recognisable in the fluid drawn off, either by simple microscopical examination or by culture-experiments. Widal and others, by centrifuging the slightly turbid fluid thus obtained from cases of tubercular meningitis, have found a considerable number of lymphocytes and large mononucleated leucocytes, which are said to be found only in forms of meningitis, though not peculiar to tubercular meningitis.

For the diagnosis of tubercular from the simple form of meningitis, and from 'posterior basic meningitis' see pp. 978 and 984.

PROGNOSIS.—Death is well-nigh certain within three weeks, or at most a month, from the date of the invasion-symptoms of tubercular meningitis. When the disease has arrived at a stage permitting of pretty certain diagnosis, hope rather than rational expectation may still hold out a chance of recovery. Although instances of this have been said to occur, they are of extreme rarity. If the course of the disease is to be modified by treatment, it must be during those early stages when we are capable of forming only a provisional or tentative diagnosis. In these stages, however, some good observers have hitherto been inclined to think that under judicious treatment the development of the disease may be arrested. This view may quite possibly, and even probably, be an erroneous one. Proof of such a position, or of its opposite, is, from the nature of the case, impossible.

TREATMENT.—From what has just been said, it will be seen that anything like curative treatment is only to be thought of in regard to the early or premonitory stage of the disease, or of conditions of health indistinguishable therefrom. Here the writer thinks he has seen decidedly good results from one to six grains of iodide of potassium, according to the age of the child, administered three times a day, with small doses of cod-liver oil; at the same time attending to the state of the bowels, and giving suitable doses of bromide of potassium at night, till the restless condition with disturbed sleep has passed away.

When the disease definitely declares itself or is further advanced, we may perhaps be able to diminish pain by the application of cold to the head; but we only aggravate the sufferings of the patient by the use of blisters, tartar-emetic ointment, or other irritating applications, such as were often had recourse to by our predecessors. Bromide of potassium may do something to keep convulsions in check, though at other times it seems to be quite powerless, and drugs of this type should never be employed in later stages of tubercular meningitis, unless there is some strong indication for their use. Chloral hydrate, again, is probably a dangerous drug for a patient, the action of whose heart is already so seriously interfered with; though chloroform inhalations may be had recourse to in an extreme case where persistent convulsions cannot otherwise be checked. Beyond this the child needs the most careful nursing, and to be well supported with strong beef-tea and milk, and occasionally with stimulants, by the mouth, so long as it is capable of taking food, but later, if need be, by means of a nasal tube. Attention must also be paid to the bowels, which are often best relieved by means of enemata. In this way, if the patient's case is to prove one of those rare and exceptional instances in which recovery is possible, we at all events do nothing to thwart the course of natural processes which have a chance, however small, of terminating in recovery. Lumbar puncture as a means of cure is useless.

H. CHARLTON BASTIAN.

4. Posterior Basic Meningitis.—**SYNON.**: Chronic Basilar Meningitis.—This disease occurs most commonly in infants, and is characterised chiefly by persistent head-retraction with vomiting. It is an infective form of leptomeningitis, distinct both from tubercular and from secondary suppurative meningitis. It is probably identical with the sporadic cases of so-called epidemic cerebro-spinal meningitis, but there are slight differences, both bacteriological and clinical, which make it perhaps desirable for the present to describe the posterior basic form as a separate condition.

ÆTIOLOGY.—It occurs most often during the first nine months of life; it is very rare after the end of the second year. Girls and boys are equally liable. The onset is usually in winter or spring; more than half the cases begin during the first four months of the year. It has occurred in many large towns and cities, but no evidence of contagion or of epidemic spread has been observed.

BACTERIOLOGY.—The exciting cause of the inflammation in the pia-arachnoid is a micro-organism, the diplococcus of posterior basic meningitis, which is probably identical with the *Diplococcus intracellularis* of epidemic cerebro-spinal meningitis. Until recently this was confused with the pneumococcus, from which it differs in many particulars. The diplococcus has been found in the cerebro-spinal fluid by lumbar puncture during life, and *post mortem* in the exudation at the base of the brain and on the spinal cord. It gradually disappears, however, after a varying time, so that in some cases three or four weeks after the onset of the disease no micro-organisms may be found. It is this tendency to spontaneous disappearance of the diplococcus which probably accounts for the clinical fact that a certain proportion of the cases recover.

SYMPTOMS.—The onset is almost always acute. An infant vomits, and is fretful or drowsy. At the same time, or it may be a few days later, the head is noticed to be drawn back stiffly, and the child cries if any attempt is made to push it forward. Sudden screaming without apparent cause is sometimes an early symptom, and in about one-third of the cases convulsions occur at the onset. Some fulness of the anterior fontanelle may be present at this stage; at a later period the bulging fontanelle may attract even the mother's notice. Head-retraction is the most constant and characteristic feature of the disease. It is almost always an early occurrence, sometimes it is the first symptom noticed. It varies in degree in different cases, and in the same case at different times; it may be so slight as to be only just noticeable, but more often it is well marked, and in some cases is so extreme that the occiput almost touches the buttocks. The opisthotonos may be limited to the cervical spine, or may affect also the dorsal and lumbar portions. With this opisthotonos there is often some rigidity of the limbs; the shoulders also may be strongly retracted. Convulsions may, as already mentioned, occur at the onset, but after this they are not a marked feature of the disease, and in some cases they are absent throughout. The face often has a staring appearance, which is due partly to spasmodic retraction of the upper eyelids, so that the sclerotic is seen above the cornea, and partly in some cases to the fact that the child is blind. Blindness occurs in about one-third of the cases. It comes on gradually, and has been noticed as early as the end of the first week. In cases which have recovered sight has returned completely after several months. The loss of sight does not correspond with any change in the fundus oculi, and the light reflex is retained in such cases, although it is sluggish. It would seem therefore that the blindness is central in origin. Optic neuritis very seldom occurs; nystagmus, usually slight and transient, is sometimes observed; squint is present in about half the cases, but is usually very slight, and may only be noticeable occasionally. Paralysis of any other cranial nerves, or of any of the limbs, is very rare. Grinding of the teeth and champing movements of the lower jaw are common in this condition; it seems likely that they are due to cerebral irritation. Tactile sensation seems to be unaffected. There is no evidence of any general hyperæsthesia, such as is found in epidemic cerebro-spinal meningitis. Deafness was observed by the writer only once in forty-five cases. The knee-jerks are usually brisk, and in the chronic stage of the disease may be definitely exaggerated with ankle-clonus: the superficial reflexes are normal. The temperature is raised at the onset, and in some cases remains high for two or three weeks, and then gradually falls; in others it falls after the first few days, and then remains normal. Less often there is irregular pyrexia throughout the illness. When exhaustion becomes extreme the temperature sometimes becomes subnormal: a fatal ending may be preceded by sudden hyperpyrexia. The pulse is usually regular, but rapid. Respiration, especially in the later stage of the disease, often shows a cyclical irregularity; long pauses alternate with series of rapid respirations, which, however, lack the rhythmical increase and decrease in depth which is characteristic of the Cheyne-Stokes breathing. Vomiting is usually a prominent symptom; it is more persistent than in

tubercular meningitis, and may occur almost daily throughout the illness. Constipation is not so marked a feature as in the tubercular disease; indeed, in the chronic stage there is sometimes troublesome diarrhoea. In most cases the infant gradually wastes; food is taken badly, and with increasing emaciation and exhaustion death occurs.

COMPLICATIONS.—The most serious and the most frequent is hydrocephalus. Within a few weeks of the onset of the meningitis measurements will often show a definite increase in the size of the head. The anterior fontanelle becomes full and tense; and as the intracranial pressure increases there may be some downward rotation of the eyeballs, so that the cornea is unduly covered by the lower eyelid. The hydrocephalus seldom reaches any extreme degree, such as is met with in congenital cases; but it is probably one of the most important factors in the mortality of posterior basic meningitis; for while the inflammation of the meninges tends to subside spontaneously, and in some of the fatal cases has already completely disappeared, leaving only fibrous adhesions, the hydrocephalus which results from the obstruction produced by those adhesions tends to be steadily progressive. A much less common complication is an inflammation about the joints, one or more of which become red and swollen. In some cases, at least, the inflammation is found to be entirely outside the joint—it is, in fact, a peri-arthritis. This condition has been shown to be due to the same diplococcus as is found in the meningeal exudation. As in other exhausting conditions, such accidental complications as bronchitis or bronchopneumonia may supervene, especially towards the end of the illness.

MORBID ANATOMY.—In the acute stage an exudation of yellowish lymph is found in the pia-arachnoid at the base of the brain and on the spinal cord. It is situated chiefly in the posterior fossa about the medulla and the inferior surface of the cerebellum, particularly in the reflection of arachnoid which passes from the medulla to the cerebellum. It extends forward usually to the optic chiasma, and sometimes along the Sylvian fissures; in rare cases there is also a trace of exudation along the sulci up to the vertex. The fluid in the ventricles is often slightly turbid, and there may be a deposit of lymph at the bottom of the cornea, or in the third or fourth ventricles. Even at this stage there is already some adhesion of the medulla to the cerebellum, and the foramina of Luschka and Majendie are more or less blocked by the exudation, so that the ventricles are distended by excess of fluid. On the spinal cord the exudation is most marked in the lumbar region, and more on the posterior surface than the anterior.

In the cases which die at the end of three or four months all exudation may have already disappeared, and only thickening and opacity of the meninges remain, with matting of the medulla to the cerebellum by adhesions, so that extreme distension of the ventricles has resulted. After such subsidence of the meningitis a fresh outbreak of acute inflammation may occur. The *post-mortem* appearances then show a combination of past and recent meningitis. This observation is in accordance with the bacteriological evidence that even where the meningitis has subsided, in rare cases the specific micro-organism is still present in the lateral ventricles at least three months after the onset of the disease.

DIAGNOSIS.—Persistent head-retraction with vomiting in an infant is strong evidence of posterior basic meningitis. The conditions most often confused with it are tubercular and suppurative meningitis.

(1) Posterior basic is distinguished from tubercular meningitis chiefly by the much more marked and persistent retraction of the head, but also by the earlier age at which it occurs—tubercular meningitis is rare under six months of age, and occurs most often in the second year—its more acute onset, the slightness or absence of ocular paralyses, the absence of paralysis of other cranial nerves, the presence of blindness without optic neuritis, and the much slower course. (2) From suppurative meningitis it is distinguished not only by the marked retraction of the head, and much longer duration, but also by the absence of any obvious focus of infection. Suppurative meningitis is usually fatal in a few days, and is almost always secondary either to some pneumococcal lesion, pneumonia or empyema, or to ear-disease or some general pyæmic condition. (3) From epidemic cerebro-spinal meningitis the posterior basic variety has been distinguished by its special incidence on the earliest months of life, the absence of any tendency to become epidemic, the absence usually of the herpes and rashes which are often a marked feature in the epidemic disease, the absence also of the affections of eyes and ears, and lastly the less acute course. No great stress, however, can be laid on such differences, and in the writer's opinion there is little doubt that posterior basic meningitis should be regarded as a sporadic manifestation of the same disease.

Head-retraction does not necessarily indicate meningitis. It may be due to reflex irritation from ear-disease or from teething. Infants also with severe respiratory disease sometimes keep the head thrown back, apparently to assist the extraordinary muscles of respiration. The withdrawal of cerebro-spinal fluid by lumbar puncture has been advocated as a method both of diagnosis and of treatment. No amount of care, however, can render such a method entirely free from risk; and although it may occasionally be advisable, it cannot be recommended as a routine practice.

PROGNOSIS.—This form of meningitis is much less hopeless in its prognosis than tubercular or suppurative meningitis. Recovery occurs in about 10 per cent. of the cases. With recovery, however, there may be mental impairment, which may or may not be associated with some degree of hydrocephalus. A fatal result may occur in the acute stage, three to five weeks after the onset. In nearly half the cases, however, death does not occur until the third or fourth month of the illness.

TREATMENT.—The administration of mercury, either by mouth or by inunction at the back of the neck, or over the abdomen, is worthy of trial. In some of the cases which have recovered this method of treatment has been adopted, and it is possible that it may hasten the absorption of the inflammatory exudation.

Potassium iodide has been used with the same object; but as aggravation of the vomiting has appeared to be due to it, this drug should be given with caution.

The application of ice to the back of the head and neck may have some effect in controlling the inflammation, certainly it seems to check the vomit-

ing in some cases. The use of blisters or other counter-irritants cannot be recommended. They are of very doubtful value, and easily cause troublesome ulceration in the delicate skin of an infant. Pain must be relieved by opiates if necessary. If vomiting is persistent, trial may be made of dilute hydrocyanic acid, in doses of quarter to half a minim for an infant six months old. Feeding is often difficult, and it may be necessary to feed through a nasal or oesophageal tube. Every effort should be made to maintain nutrition, and in the chronic stage, and especially during convalescence, malt-extract or cod-liver oil may be useful. The spontaneous subsidence of the meningitis, and the fact that the later symptoms appear to be due chiefly to mechanical obstruction of the cerebro-spinal passage by adhesions causing hydrocephalus, have raised hopes that it may be possible to establish an artificial drainage of the ventricles by operation, and so to save life. In one case, recorded by Lees, an apparently permanent cure was obtained by the method of subdural drainage; but in other cases treated by this internal drainage, or by the earlier method of external drainage, the results have been disappointing: in many of them a fatal ending, with sudden hyperpyrexia, has followed within a few hours after the operation.

G. F. STILL.

5. Pachymeningitis Hæmorrhagica Interna.—SYNON. : *Hæmatoma duræ matris*; Subdural false membrane; Arachnoid cyst; Fr. *Pachyméningite*; Ger. *Pachymeningitis*.

DEFINITION.—A deposit lying between the dura mater and the pia-arachnoid, and consisting of actual blood or blood-clot, or of the more or less organised remainder of one or more previous hæmorrhages, or possibly of abnormal constituents of the subdural fluid which have transuded from the blood-vessels of the pia-arachnoid or dura mater.

GENERAL ÆTIOLOGY.—This deposit is almost confined to certain varieties of insanity associated with dementia, and to general paralysis of the insane. The frequency with which it occurs is variously stated by different observers. According to Bevan Lewis, it exists in 5·2 per cent. of all cases of insanity, while Wigglesworth found it in 8·47 per cent. of his cases, and Ford Robertson in 25·5 per cent. From the records of the first 1,626 autopsies performed at Claybury, the writer has found a percentage of 9·76 of the males and 5·54 of the females, or 7·75 of the whole of the cases. In the last 300 cases which the writer has himself observed, the percentage has been much higher than this. A subdural deposit rarely occurs in sane individuals, but at times it is found in children, usually as a result of injury, and in advanced age or after certain exhausting diseases such as the specific fevers and the diseases of the blood.

PATHOLOGY AND MORBID ANATOMY.—The occurrence of subdural deposits has till recently been explained on one of two hypotheses. The first, that the deposit is inflammatory in origin, may be a true explanation of certain traumatic cases; the second, that it is due to an effusion of blood into the subdural space, is largely accepted by alienists in this country, and is supported by the fact that injection of blood into the subdural space of animals may result in the formation of a typical false membrane. According to Wigglesworth, subdural hæmorrhage is often compensatory, in association with wasting of

the hemispheres and general or localised congestion of the meninges. More recently G. M. Robertson (1893) has suggested that a sudden lowering of intracranial pressure is an important factor in causing rupture of the dural vessels. Still more recently Ford Robertson has minutely described certain degenerative conditions of the dura mater in the insane which he considers to be important factors in the production of subdural deposits, though he traces these deposits in some cases to hæmorrhage from pial veins. It has been proved by the writer that the morbid appearances inside the skull-cap, which occur in many cases in ordinary insanity, namely, chronic degeneration of the dura mater, excess of intra-cranial fluid and chronic thickening of the pia-arachnoid, &c., are the macroscopic equivalents of, and vary in degree with, the amount of dementia existing, and are independent of the duration of the insanity. These morbid appearances are all especially evident in general paralysis, which is an acute progressive dementia, and in which subdural deposits are especially prone to occur. With reference to the occurrence of these deposits, the most important factor is probably the excess of intra-cranial fluid, or 'hydrops ex vacuo,' which occurs in dementia. This fluid has in general paralysis been shown by Halliburton and Mott to contain choline, and it is certainly abnormal in many cases of ordinary insanity, and is occasionally blood-stained. Externally this fluid interferes with the normal relations between the dura mater and the pia-arachnoid. Especially in the regions where stagnation is most likely to occur, namely, in the anterior and middle fossæ, the former membrane undergoes chronic degeneration, resulting in roughening of the surface, &c. The pia-arachnoid, chiefly over the frontoparietal region, where most of the neuronc degeneration has occurred, makes a hopeless attempt at the formation of replacement- or scar-tissue. Lastly, inside the ventricles, a similar morbid condition to that of the dura, namely, granularity of the ependyma, results, and this also occurs chiefly in the regions most subject to stagnation of the cerebro-spinal fluid, as in the lateral ventricles behind the foramina of Munro, and the lateral sacs and the calamus of the fourth ventricle. This granularity is probably allied to the usual degenerative condition of the ependyma of the central canal of the spinal cord in adults, aggravated by contact with abnormal cerebro-spinal fluid.

The morbid conditions above described are the physiological results of the loss of cerebral substance caused by the neuronc degeneration of dementia reacting on the mechanical conditions existing within the skull-cap. In the dementia of general paralysis the liability to blood-effusions is increased by the epileptiform seizures which are an almost constant symptom of the disease, and which necessarily cause considerable alterations in intra-cranial tension, and the same remark applies also to certain of the insanities associated with epileptiform seizures. Blood having been effused inside the skull-cap, between the dura and the pia-arachnoid, it will, if small in amount and on the convexity, be deposited on the dura of the vertex if this be roughened, or on the basal dura, which is so frequently in a degenerate condition. If the effusion be larger in amount, the parts on which it is deposited will depend largely on gravity, and it is consequently found to a greater or a less extent in the base of the skull above the tentorium. If, finally, the effusion be sudden and

large, or occur in successive small quantities, the blood, as a rule, clots *in situ*. This condition usually exists at the vertex, where, owing to the arrangement of the veins, venous congestion is likely to occur, and to result in rupture of one or more of the pial veins. The result, if the patient recovers from the immediate effusion, is a deposition in the subdural space of thinner or thicker brown films which usually adhere to the dura, but are readily detachable from it; of semi-organised membranes or cakes of blood, which in many cases contain semi-fluid material; or even of calcareous masses. In some cases, on removing the dura, the whole vertex is covered with a thin transparent membrane which may be ballooned out by fluid, and resemble an additional arachnoid. This membrane may even line the whole cavity of the cranium, and extravasations of blood may occur between it and the dura mater, here arising from dural vessels, or between the membrane and the pia-arachnoid, owing to rupture of pial veins. In the case of the thinner transparent films and membranes, it is possible that they arise by deposition, on the degenerated surfaces ready for their reception, of abnormal constituents of the cerebro-spinal fluid, which may be due to neuronie degeneration or to simple transudation from the altered vessels under the abnormal intra-cranial conditions which exist. The occasional cases where no subdural deposit exists, but in which the subdural fluid is blood-stained, and the numerous instances in which old or recent hæmorrhages into the pia-arachnoid exist alone, or in conjunction with the subdural deposit, are probably either conditions prior to the development of a deposit, or may be of a similar nature and have a similar origin. Under certain circumstances similar deposits may occur as a result of accidental hæmorrhages in the sane. The conditions are, however, different, for if the effusion be small, the dura and pia-arachnoid being normal, the blood will mix with the cerebro-spinal fluid and be flushed out by it; or if it exist within the pia-arachnoid it may form hæmatoidin in this position without affecting the dura. If, however, the effusion be large, it will cause symptoms of intra-cranial pressure, owing to the relative absence of cerebro-spinal fluid from the healthy cranium, and will probably either kill the patient or be removed by operation. In dementia, on the other hand, extra-cerebral effusion of blood is prone to occur; the dura is in a degenerate condition which offers a surface for the deposition of the blood; and, lastly, the excess of cerebro-spinal fluid which is present allows space, without increase of intra-cranial pressure, for even enormous effusions of blood. It is hence probable that the *chief causes of subdural deposit* are the degenerative conditions which develop inside the skull-cap during the progress of dementia, together with certain factors which produce a more or less marked condition of venous stasis, namely, epileptiform seizures and thrombosis of important venous channels. This is prone to occur owing to the anatomical arrangement of the veins entering the superior longitudinal sinus.

It is not improbable that slight injuries, &c., may give rise to a subdural deposit in many cases, especially as so many of the subjects are restless, feeble, and liable to fall and bruise themselves. The writer has recently seen a case of general paralysis in which, some weeks before death, the patient, from a fall, developed extremely marked bruising of the

forehead, eyes, and right temple. At the autopsy, a reddish-brown membrane was found in the right middle fossa and in both anterior fossæ of the skull. In another general paralytic, who died of extensive intra-cranial hæmorrhage, affecting the right anterior quadrant and the left posterior quadrant of the encephalon, marked and recent bruising of the right eye and the right temple as far back as the right parietal eminence existed. In a third patient, suffering with epilepsy, who died of erysipelas affecting the right eye, the right temple and the neighbouring parts, a recent subdural deposit of blood existed in the region corresponding to the external lesion.

The thinner membranes usually occur in very old persons, or in association with such exhausting diseases as phthisis and asylum dysentery.

In patients not insane, subdural hæmorrhage may result from injuries during birth, or it may develop in young children from simple strain, as in whooping-cough, &c., or later in life from blows or falls. It has also been described as occurring in the old and feeble, especially when these patients are suffering from exhausting diseases.

SYMPTOMS.—But little can be said concerning the symptomatology of subdural deposit owing to the rarity with which it is diagnosed *ante mortem*. The symptoms occurring in a typical case of the disease are described on the plate facing p. 576. For the symptoms of subdural hæmorrhage in the sane, the reader is referred to the article MENINGES, CEREBRAL, Hæmorrhage into.

DIAGNOSIS.—In cases of general paralysis the seizures and the general mental condition of the patient, as a rule, completely obscure the symptoms due to subdural hæmorrhage. In the fairly numerous cases where rupture of a pial vein follows intense venous engorgement, due to thrombosis of the superior longitudinal sinus, the great anastomotic vein, or other important venous channels, the general symptoms due to the thrombosis would, as a rule, obscure those due to the hæmorrhage. In the less severe cases, and also in those patients who suffer from the epileptiform seizures which frequently occur with degeneration of the cortical arteries, or result from old-standing or slowly progressive lesions of the cortex, the occurrence of subdural deposit will not even be suspected.

PROGNOSIS.—Relatively few patients die directly from subdural hæmorrhage. In the majority of cases, death ensues from the primary disease or from some intercurrent complication.

TREATMENT.—That of ordinary apoplexy. See also the following article.

J. S. BOLTON.

6. Hæmorrhage into Cerebral Meninges.

SYNON.: Fr. *Apoplexie Mèningée*; *Hémorrhagie Mèningée*; Ger. *Hirnhautblutungen*.

DEFINITION.—Effusion of blood in one or other of the following situations: (1) Between the bone and the dura mater; (2) between the dura mater and the arachnoid (into the so-called 'arachnoid sac'); or (3) beneath the arachnoid and into the meshes of the pia mater.

ÆTIOLOGY.—The first of these varieties of meningeal hæmorrhage has an almost exclusively traumatic origin; being a result of falls or blows which occasion the rupture of one of the meningeal arteries lying between the bone and the dura mater. Caries of the bone may in very rare cases lead to

such a hæmorrhage by causing erosion of one of the meningeal arteries.

The other two varieties are not so distinctly separated from one another, since a hæmorrhage occurring in the pia mater, if large, is very apt to break through the arachnoid, and thus lead to effusion of blood into the 'arachnoid sac;' and this whether the primary effusion has been the result of a traumatic injury, or is a sequela of some general or local disease. Effusion into the arachnoid may also occur as a result of rupture of some vessel on the inner surface of the dura mater; this being probably a rare consequence of injury. *See also* PACHYMENINGITIS HÆMORRHAGICA, p. 985.

Effusions of blood are occasionally found beneath the arachnoid which have not originated there, but which have come to the surface, by laceration of brain-substance, from some intracerebral hæmorrhage; or they may have been caused by intraventricular hæmorrhages, finding their way into the fourth ventricle, and thence into the subarachnoid tissue of the pons and cerebellum.

In very young children, whose vessels are presumably healthy, bleeding into the arachnoid may occur from any unusual amount of strain. This occasionally takes place at the time of birth, especially during prolonged labours. Indeed, according to Cruveilhier, arachnoid hæmorrhage is the cause of the death of about one-third of those infants who die almost immediately after birth; and is of extreme frequency in cases in which the labour has been difficult or protracted (Spencer). A little later on in life, a similar accident may occur during paroxysms of whooping-cough, or during other spasmodic respiratory conditions, in which the return of venous blood from the head is impeded. Later still, an arachnoid hæmorrhage not infrequently follows a fall or blow upon the head, or it may result from the rupture of an aneurysm on one of the larger vessels about the base of the brain—especially the basilar or one of the middle cerebrals. Small subarachnoid hæmorrhages, often multiple, are not infrequently produced by the occurrence of thrombosis in the superior longitudinal sinus. They may also occur in persons suffering from scurvy or leucocythæmia. Lastly, they may be met with as one out of the many forms of lesion occurring in patients suffering from general paralysis of the insane.

Meningeal hæmorrhages are decidedly more common in males than in females—in the proportion of about three to one. They do not, however, like cerebral hæmorrhages, occur with progressive frequency as age advances, but are much more uniformly distributed through the different decades of life.

ANATOMICAL CHARACTERS.—When death takes place soon after blood has been effused into the arachnoid as well as in the other situations, it is found in an easily recognisable condition. This is by no means the case, however, after the lapse of many months or even years; then, in the case of small hæmorrhages, we may meet with mere yellowish or rust-coloured stains; while where they have been of larger size, we may find decolorised cyst-like bodies, either free or adherent—or else there may be decolorised membranous masses, adhering mostly to the parietal arachnoid. Where the size of the clot has been large, the surface of the brain is more or less pressed upon, so that some atrophy of its substance follows. *See also* PACHYMENINGITIS HÆMORRHAGICA, p. 985.

SYMPTOMS.—The symptoms attendant upon meningeal hæmorrhage will necessarily vary a great deal in severity, according to the amount and suddenness of the effusion. These symptoms are, moreover, in the great majority of the traumatic cases obscured by those depending upon the mere shock and concussion of the brain, which the original accident or blow occasions.

Where subarachnoid hæmorrhages occur in the course of thrombosis of the longitudinal sinus, no distinctive symptoms are as a rule produced; and those of the primary affection are themselves only too variable and difficult of recognition. Again, where subarachnoid hæmorrhages occur in the course of purpura, leucocythæmia, or allied affections, the amount of blood effused is usually too small to produce definite or recognisable symptoms. At most, the abrupt onset of pain in the head, vertigo, or mental confusion, may give rise to a suspicion that such an event has occurred.

Where a large hæmorrhage takes place beneath and into the arachnoid sac, over one hemisphere, or over both, either as the result of a fall or blow, or from the bursting of an aneurysm on one of the large arteries at the base of the brain, a profound coma is produced which may prove rapidly fatal—that is, in the course of a few minutes or a few hours. Where the amount of blood effused is less, and where it is poured out more gradually at first, there may be premonitory symptoms, in the form of sudden headache, vertigo, mental confusion, vomiting, or convulsions, rapidly followed by unconsciousness. At first there is generally complete relaxation of all the limbs; but later—after some hours or days—the weakness may be distinctly unilateral, that is, of hemiplegic type, though sometimes with very slight implication of the face. There may also be twitches or rigidity of the limbs on one or both sides. On recovery of consciousness there may be no distinct loss of sensibility, only numbness, in the limbs; and the paralysis may after a time grow less up to a certain point, or gradually disappear.

DIAGNOSIS.—In many of the slighter forms of hæmorrhage into the cerebral meninges diagnosis is, for the reasons specified, almost impossible.

In the more severe cases a sudden apoplectic attack is produced, agreeing very closely with that occasioned by some of the most serious forms of intracerebral hæmorrhage. Causal conditions, especially when they have been traumatic, together with the possible youth of the patient, may in some cases help us to diagnose a large arachnoid hæmorrhage from a copious bleeding into the lateral ventricles, or from a sudden hæmorrhage into the middle of the pons Varolii; though it should be borne in mind that in the former of these two conditions the pupils are almost always widely dilated, while in the latter they are as constantly contracted and insensitive; whereas they are likely, so far as the writer's observations have gone, to be in a more intermediate condition in arachnoid hæmorrhage.

PROGNOSIS.—In the case of arachnoid hæmorrhages, whether large or of only moderate volume, should the patient survive the first effects of the effusion (and, it may be, of the injury which caused it), danger to life is no longer to be feared. The only question then is as to the amount of paralysis, mental impairment, or of irritability with cephalalgia, which may remain; or whether or not a

tendency to convulsions may be set up, as a consequence of the original injury and lesion.

TREATMENT.—The treatment of a case of meningeal hæmorrhage does not differ from that appropriate for cerebral hæmorrhage. Perfect rest in the recumbent position, with the head slightly raised, is essential. Cold to the head may be conjoined with hot applications and mustard plasters to the lower extremities. For other indications and details of treatment we must be guided by the varying conditions of the patient. In some cases (especially where the hæmorrhage has been between the dura mater and the bone) the aid of the surgeon has been sought, who, by trephining and giving exit to much of the extravasated blood, has either cured or greatly mitigated the condition of the patient. During convalescence, in the more favourable cases, we must pay great attention to the general health, and above all protect the patient from overwork or excitement of any kind.

H. CHARLTON BASTIAN.

7. Traumatic and Secondary Spinal Meningitis.—**ÆTIOLOGY.**—In the case of the cerebral meninges, inflammation as a result of traumatic injuries is more common than as a phenomenon secondary to disease of the bone or of the scalp. The proportional frequency of these modes of causation is, however, somewhat reversed in the case of the spinal meninges; partly because the head is more liable than the spine to suffer from direct injuries, and partly because disease of the spine and of adjacent parts occurs with considerable frequency in such a manner as to be capable of exciting a secondary inflammation of the spinal meninges. Among the various efficient *traumatic* influences may be mentioned fractures and dislocations of the vertebræ, and stabs or other penetrating wounds implicating the contents of the spinal canal; while among the most frequent morbid conditions, in the course of which there may be a *secondary* development of spinal meningitis, we must cite the following: Caries and tubercular disease of the vertebræ; syphilitic gummata; deep sloughing bed-sores in the sacral region; cancer of the vertebræ; and, more rarely, inflammation of some part of the thoracic or abdominal parietes contiguous to the spinal column, and capable of spreading to the spinal canal from within.

ANATOMICAL CHARACTERS.—In all these cases the signs and products of inflammation may be found in one or other, or in both, of two situations; that is, either implicating the dura mater, principally on its external surface, when we have the condition commonly known as *spinal pachymeningitis*; or affecting the surface of the arachnoid so as to produce a *spinal arachnitis*. Thus the same kind of limitation in the distribution of the inflammation is apt to occur, when it starts under the influence of such causes, as is found to obtain in regard to the traumatic or secondary inflammations of the cerebral meninges. Perhaps there is in the case of inflammation of the spinal membranes, however, a rather more distinct tendency for such inflammations to spread, so as to involve the subjacent pia mater, than is the case in the parallel inflammations of the cerebral meninges.

In *spinal pachymeningitis* the dura mater itself is thickened and more vascular than natural, this being seen more especially on its outer surface; and both it and the surrounding connective tissue are

covered or infiltrated either with yellowish lymph-like matter, or with actual pus. The internal surface of the dura mater may also be more or less covered with inflammatory products. The nerve-roots passing through the membrane are likewise generally affected by the inflammatory process, and they may show signs of compression or even of atrophy. Such inflammation may be either limited to the region of two or three vertebræ, or it may affect more or less the whole length of the spinal membranes.

A more chronic form of spinal pachymeningitis has been observed by Charcot and others, affecting principally the inner layers of the dura mater in the cervical region. In this condition, which is described by the author above named as *pachymeningite cervicale hypertrophique*, there seems to be a considerable hyperplasia of tissue-elements in the inner layers of the dura mater, which is apt to develop into an overgrowth of almost cicatricial hardness, often made up of concentric laminæ. These are frequently adherent to the arachnoid and to the pia mater, which also become more or less thickened. In these latter cases, especially, not only are the spinal nerve-roots greatly damaged, but the spinal cord is itself more or less compressed and softened, so that distinct paralytic symptoms, with muscular rigidities or atrophy, are apt to be produced.

Where *spinal arachnitis* is superadded, or when it exists alone, we find that pus or lymph is situated on the outer surface of the visceral arachnoid, and also to a less extent on that lining the dura mater. The combination of the two conditions is rather more frequent than the existence of arachnitis alone. It is important to remember that all these forms of inflammation are very rarely, if ever, primary and idiopathic (with the exception of the more chronic variety described by Charcot), but that they occur as consequences of injury, or of certain forms of disease adjacent to the spinal canal.

SYMPTOMS, PROGNOSIS, AND TREATMENT.—As the nerve-roots are affected in these forms of inflammation, as well as in the idiopathic meningitis which implicates the pia mater (*spinal leptomeningitis*), and as the symptoms of both sets of affections are in great part dependent upon this, and are therefore in many respects similar (and by no means always capable of being accurately discriminated from one another), it would serve no useful purpose to dwell upon the symptomatology and treatment of spinal pachymeningitis and arachnitis alone. The reader is, therefore, referred to the corresponding sections in the next article.

H. CHARLTON BASTIAN.

8. Idiopathic and Tubercular Spinal Meningitis.—**SYNON.**: Simple and Tubercular Spinal Leptomeningitis.

Simple spinal meningitis of idiopathic origin, and tubercular spinal meningitis, are affections so closely related to one another, both in their clinical and pathological aspects, that no advantage whatsoever would be derived from considering them separately. In each case we have to do with an inflammation involving the spinal pia mater, so that the products of inflammation are situated beneath the arachnoid membrane. In order to distinguish these from other forms of meningitis, such as pachymeningitis and arachnitis, it is desirable that we should use some special term, such as *leptomenin-*

gitis, which is now employed as a distinctive appellation for an inflammation affecting the pia mater, whether cerebral or spinal.

In regard to the extent or area of this kind of inflammation, it must be said that the tubercular variety always involves the presence of a similar inflammation at the base of the brain, though the contrary position is not true—that is to say, the tubercular inflammation may exist at the base of the brain alone, without involving the spinal meninges. Of the non-tubercular forms of spinal leptomeningitis there are two varieties, and of these one form always involves the membranes at the base of the brain and the spinal meninges simultaneously (*see MENINGITIS, EPIDEMIC*, p. 992). The other form may or may not simultaneously involve the membranes at the base of the brain, so that we have in these cases either a 'simple sporadic cerebro-spinal meningitis,' or a 'simple spinal meningitis.'

Whenever the inflammation has a 'cerebro-spinal' distribution, no confusion is involved by retaining the use of the simpler term 'meningitis,' as it is generally understood that forms of inflammation having such a distribution involve the pia mater especially. But in place of the name 'spinal meningitis,' if we mean to imply that the inflammation affects the same tissue, it is best to use the more special and distinctive term 'spinal leptomeningitis.'

From what has been said above, it will be understood that the symptoms resulting from meningitis involving the base of the brain alone, or together with serous effusion and softening of the walls of the ventricles (which, as we have seen, so frequently co-exists with inflammation of the membranes in this situation), have been principally studied in the purely cerebral forms of tubercular meningitis. On the other hand, the symptoms resulting from spinal leptomeningitis are best studied in the simple forms of this disease. It will also be evident that the simple and the tubercular forms of cerebro-spinal meningitis are likely to agree to some extent in their symptomatology with that of the disease known as 'epidemic cerebro-spinal meningitis.' *See* p. 992.

ÆTIOLOGY.—Spinal leptomeningitis is most prone to occur in children and in young persons; and is more frequent in males than in females. Persons who are badly fed, and live under very unfavourable sanitary conditions, are more liable to be attacked than those who are healthy and surrounded by opposite conditions.

For the tubercular form the exciting causes are all such influences or conditions, whatever they may be, as determine the outbreak of acute tuberculosis. The affection of the spinal meninges may be either an extension of the inflammation originally existing at the base of the brain alone, or it may be another independent manifestation of the general disease developing within the spinal canal simultaneously with the cerebral meningitis. *See* MENINGES, CEREBRAL, Inflammation of, Tubercular.

For the simple or non-tubercular form, the exciting causes are various, but the best established of them would seem to be these: Exposure to cold, or cold and wet, in various forms; certain acute diseases, or the period of convalescence therefrom; concussion of the spine, as from falling down stairs, or in other ways; wounds affecting the spinal cord or its membranes, as in stabs of various kinds; or fracture and dislocation of the vertebrae.

The last modes of causation mentioned are simi-

lar to those which obtain for spinal pachymeningitis and arachnitis; for, although these latter conditions may be excited alone under such traumatic influences, they may also in certain cases, and especially arachnitis, be excited in association with a spinal leptomeningitis. Precisely the same kind of thing has also to be said in regard to the occasional action of other causes, such as caries of the vertebrae, deep, sloughing bed-sores in cases of paraplegia, or other instances of inflammatory processes contiguous to the spinal canal. Any of these latter conditions may also set up a leptomeningitis, in association with one of the other forms of meningeal inflammation.

A spinal leptomeningitis may spread so as to implicate the base of the brain; or a cerebral basal leptomeningitis may subsequently implicate the spinal membranes; or, lastly, the inflammation may appear in both regions simultaneously, and thus be from the first cerebro-spinal in seat. The writer has of late seen several cases of the tubercular variety belonging apparently to this latter category; but until the spinal canal has been regularly opened for some time in necropsies of persons dying from this disease, we shall be unable to say what is the exact numerical proportion of such cases as compared with those which are simply cerebral in type. The bulb may be comparatively free from lymph, and yet an inflammation of the spinal meninges may be well-marked. There must, therefore, be a routine opening of the spinal canal for the decision of this question, and not a mere casual inspection of its upper extremity through the foramen magnum.

ANATOMICAL CHARACTERS.—According to the stage of the disease at which death takes place, we may meet with the inflammatory process in one or other of three different stages: (1) that of greatly increased vascularity of the spinal pia mater; (2) one in which, in addition to the increased vascularity, gelatinous serum, lymph, or pus exists in the meshes of the pia mater, often more marked in amount along the posterior columns. This latter is the condition commonly met with; but in rare cases, where patients have survived an acute attack, we may find (3) certain residuary chronic changes in the form of thickenings, opacities, and undue adhesions of the pia and arachnoid to the spinal cord, which perhaps may itself show a more or less marked condition of peripheral sclerosis.

In the tubercular variety we frequently have to do with a mere gelatinous serum, or thin greenish-yellow lymph (similar to that met with at the base of the brain), rather than with actual pus, in the meshes of the pia mater. Careful scrutiny of the vessels in the anterior fissure and in other parts may also show the characteristic 'granulations,' in the form of opalescent, whitish, or yellowish-white specks.

In both forms of the disease the *nerve-roots* are implicated in various ways. They are usually involved in the inflammatory process, and may be much pressed upon by lymph and other hyperplastic products. The nutrition of the cord itself is probably profoundly altered, owing to the existence of an inflammatory process affecting the network of vessels from which its blood-supply is derived; and, moreover, the organic continuity existing between the pia mater and the offshoots of connective tissue which extend into it on all sides, around the blood-vessels that penetrate its substance, makes it easy

for the inflammatory process to invade the substance of the cord itself.

SYMPTOMS.—General listlessness and a sense of chilliness have been noticed as premonitory symptoms in some cases of spinal meningitis. At other times the disease has been observed to commence with a more marked feeling of chilliness, accompanied or quickly followed by some febrile elevation of temperature, together with a full, rapid pulse. Soon there supervenes a deep-seated boring pain in the back, varying in situation according to the degree of intensity of the inflammatory process at different levels. Pains may also extend round the body in girdle fashion, and likewise into the limbs. While the pains in the back are more or less continuous, though greatly aggravated by all attempts at movement, those felt in the limbs and trunk may be only experienced when attempts to move are made. Movement excites the dorsal pain far more than pressure upon the vertebral spines, or light tapping over the same region.

Rigidity of the spine, from muscular spasm, either localised or general, and also rigidity of the limbs, or even of special muscles, may co-exist with the pains in the back and limbs. There is often an exaltation of reflex movements in the early stages of the disease, though this condition is not nearly so well marked as it is in tetanus. 'Kernig's sign' may also be present (p. 820).

At the same time marked hyperæsthesia of the skin exists over considerable regions of the trunk and extremities. The patient cannot bear to be touched, however lightly; and still less can he endure to be moved. He is irritable or plaintive if these proceedings be attempted. Owing to the varying nature and extent of the spasms, and the different degree of pain endured, the position assumed by the patient is very various in different cases.

Difficulty in defecation and in micturition often exists, especially in the early stages of the disease, and this is supposed to be due to a spasmodic condition of the sphincters. The respiration and the heart's action are principally interfered with in cases where the cervical meninges are gravely involved.

The temperature seems to pursue a somewhat irregular course, but concerning this further information is needed. It may be only slightly above the normal; and may not rise much beyond 102° , even in fatal cases, till near the end. Then it may rise considerably in the course of a few hours; while in other cases it may at this same period become depressed below the normal.

In the later stages of the disease some amount of paresis, or actual paralysis, may be noted in one or more limbs; the pains on movement and the cutaneous hyperæsthesia become less, or may indeed be intermixed with tracts in which actual anaesthesia exists. The bladder may at last be paralysed; and respiration may be most gravely interfered with, so that disturbance of this function, as well as of the heart's action, may be the actual cause of death.

These symptoms are, in all probability, as Erb maintains, due in very great part to the inflammatory and other changes by which the anterior and posterior nerve-roots are implicated. Others may be due to extensions of the inflammatory process to the substance of the spinal cord, thus leaving a somewhat uncertain minority of symptoms to be accounted for by the mere implication of the pia mater itself.

The grouping of symptoms is apt to vary much in different cases, according as there is or is not the co-existence of a cerebral meningitis; or, in the absence of this complication, according as the inflammation is more or less localised in different regions of the cord, or general in its distribution. Much will depend also upon the severity of the process, and upon the extent to which the substance of the spinal cord becomes involved in the course of the disease.

DIAGNOSIS.—Fever; pains in the back and limbs, greatly aggravated by movement; together with stiffness of the neck, trunk, or limbs, including 'Kernig's sign'; local muscular spasms; hyperæsthesia of the skin; retention of feces and urine; dyspnoea; with a tendency in the later stages to the supervention of paresis, or actual paralysis of limbs—these are the symptoms, the combination of which to a marked extent becomes almost typical of spinal meningitis.

Its complication with a basal cerebral meningitis is, among other signs, chiefly indicated by the occurrence of vomiting, headache, retraction of head and neck, slight delirium or stupor, paralysis of ocular muscles, difficulty in deglutition, loss of speech, or convulsions. The presence of many of such symptoms may, from their great importance, tend to dwarf or obscure those due to the inflammation of the spinal meninges alone; on the other hand, if they are absent we may feel assured that the inflammation has not also involved the base of the brain.

The fact that a meningitis is spinal in seat, and unaccompanied by cerebral symptoms, is of itself exceedingly good evidence to prove that it is not the tubercular form of the affection.

To settle the question, which membranes of the cord are inflamed in any given case, we must be guided chiefly by what we can learn concerning the causal conditions and the distribution of the inflammation, rather than by any at present known differences in the grouping of symptoms. Thus inflammations of idiopathic origin, or those which are cerebro-spinal in seat, will almost invariably be found to be instances of leptomeningitis; while those set up as a result of caries of the vertebræ, or as a sequence of a sloughing sacral bed sore, are certainly much more prone to take the form of pachymeningitis, or of this in combination with arachnitis.

In reference to the diagnosis of spinal meningitis from other affections, it may be said that a very slight amount of attention to the nature of the pains and attendant conditions will suffice to avoid the mistake of supposing them to be rheumatic in nature. Similarly the absence of trismus in the early stages, and of any extremely well-marked exaltation of reflex excitability, together with the presence of severe pains in the back and limbs, will be negative and positive characters sufficient for distinguishing spinal meningitis from tetanus.

Another disease with which spinal meningitis is liable to be confounded is acute softening of the spinal cord. But the distinction should be easy in the early stages; and the history of the course of the affection will guide us later on, when symptoms of actual paralysis may have become developed. Still, in certain cases, a spinal meningitis may entail a softening of the cord to a marked extent, and then the symptoms of the primary affection will gradually be merged in those of the other which it induces.

A very rare condition, once met with by the pre-

sent writer, is, he thinks, almost impossible to distinguish from spinal meningitis—that is, where a sarcomatous or carcinomatous new-growth springs up rapidly throughout the spinal pia mater in the situation usually occupied by lymph or pus, especially when, as in the instance referred to, the disease seems to be the direct sequence of a fall from a height or over a flight of steps, and death takes place within a period of two or three months.

PROGNOSIS.—The prognosis of spinal meningitis depends a good deal upon the nature of the primary or causal conditions; upon the question whether the disease shows a tendency to extend to the cerebral meninges; upon the severity with which it implicates the cervical region of the cord; and also to some extent upon the age and general state of health of the person attacked.

Spinal meningitis is a disease which proves fatal in the course of a few weeks in a very large percentage of cases. Complete recovery is certainly a rare exception; but late and partial recovery—that is, after the disease has lasted long, and with the remainder of some amount of muscular atrophy or incurable paralysis—is a little more frequent. In such cases the disease after a time lapses into a chronic condition, and the patient very gradually recovers, except, perhaps, for such incurable sequelæ as are above mentioned. But even in these cases tending towards recovery, a relapse is most easily brought about, owing to the recommencement of the disease in an acute form.

Where spinal meningitis supervenes upon a sloughing bed-sore existing in a case of paraplegia, the end is usually not far distant. The gravity of any case of spinal meningitis is also always greatly enhanced when the disease spreads to the cerebral meninges. And, so far as the spinal meninges themselves are concerned, any great intensity of the inflammatory process in the cervical region is always of the gravest import, because of the liability to secondary implication of the cord itself in these regions, either structurally or functionally, and the bringing about from this cause of serious interference with the functions of respiration and circulation. A continuously rising temperature in such a case—to 105° and onwards—is also of fatal import.

TREATMENT.—The severity of spinal meningitis is apt to prompt to the use of active measures of questionable utility; among these may be cited free local blood-letting, the free application of ice to the spine, and active purgation. It is difficult, too, to say on what principle it is thought absolutely necessary to apply cold when we have to do with an inflammation within the spinal canal or within the cranium, while we almost always apply heat externally in the case of an inflamed pleura, an inflamed peritoneum, or even an inflamed area of skin. Probably the application of ice in such cases tends to alleviate pain, so that where this is great its use may bring much relief to present suffering, when hot applications would only aggravate it. But were it not for the fact that in meningeal inflammation (whether spinal or cerebral) increased fulness of vessels around sensitive organs shut in by unyielding walls almost necessarily leads to aggravation of pain, the application of heat would probably be more beneficial than that of cold, so far as the possible resolution of the inflammatory condition itself is concerned.

The patient should certainly be kept in a cool, quiet room, and lying either on his side, or, if pos-

sible, on his face, on a comfortable bed. He should be well supplied with fluid diet of the most nourishing description, together with eggs and a moderate amount of stimulants, according to the indications presented by his symptoms and general condition.

Tincture of iodine may be painted along each side of the spine in the affected region every second or third day. Pain should also be eased by opium or morphine; in fact, an opiate treatment may be resorted to in a large proportion of the cases. When opium and morphine do not agree, or are not admissible, Indian hemp would be worthy of trial as a mere anodyne; or we must fall back upon bromide of potassium and chloral hydrate, though the latter must be used with great caution where the heart's action is slow, irregular, and seriously interfered with. Belladonna and ergot have also been recommended, on somewhat doubtful grounds, as anti-inflammatory remedies in spinal meningitis.

We ought, in fact, to endeavour to combat the most urgent symptoms as much as possible, even if we cannot, by counter-irritants and by the judicious use of drugs, modify the course of the inflammation. Also by suitable feeding and judicious nursing we should endeavour to tide the patient through the disease. And if, happily, the activity of the inflammatory process subsides, the most unremitting attention will still be required to protect the patient against a relapse. Should his condition otherwise admit of it, the absorption of inflammatory products would, in this stage, be likely to be promoted by the use of a small dose of perchloride of mercury (such as one-sixteenth of a grain for an adult), in combination with increasing doses of iodide of potassium. At the same time, every effort must be made to restore the patient's general health, and to combat the emaciation which the disease itself usually involves.

H. CHARLTON BASTIAN.

Hæmorrhage into or upon Spinal Meninges.—**SYNON.**: *Hæmatorrhachis*; Meningeal Apoplexy (Spinal).

Effusions of blood upon, between, or beneath the spinal meninges are altogether rare events, contrasting notably in this respect with the comparative frequency of parallel conditions on the side of the cerebral meninges.

ÆTIOLOGY.—Among the causes of meningeal hæmorrhages, stabs, blows, or falls will hold a first rank. After these causes we should have to cite impediments to the circulation of blood, occasioned by various respiratory or muscular spasms, occurring either in the course of whooping-cough, or during some more than usually violent convulsive attack—epileptic, tetanic, or other. The lifting of heavy weights, or other great voluntary muscular exertions, may likewise at times prove causes of spinal meningeal hæmorrhage. Occasionally, however, it occurs independently of any such, or of other readily assignable causes.

ANATOMICAL CHARACTERS.—Fluid blood or blood-clots may exist in relation with the spinal meninges in three different situations.

The most frequent site of such hæmorrhage is (1) outside the dura mater, between it and the vertebral arches. Here large clots are sometimes found, wholly or more frequently in part surrounding the dura mater in the region in which the hæmorrhage has occurred. Where the effusion is large the cord itself may be distinctly compressed,

but even smaller effusions may produce some amount of compression of nerve-roots. A clot in this situation, as in other sites, will of course become much modified in appearance with age.

Clots and more or less fluid blood may also, but more rarely, be met with (2) inside the dura mater, within the so-called arachnoid sac. This occurs perhaps most frequently as a mere sequel of a similar hæmorrhage taking place in the cerebral meninges, the blood simply gravitating into the spinal canal. Sometimes, however, especially in cases of spinal pachymeningitis, blood is actually effused in this situation—and that where the internal surface of the dura mater is much more vascular than natural. The opening of a thoracic or abdominal aneurysm may also very rarely take place into the spinal canal, and thus produce sudden and grave compression of the spinal cord.

Much smaller extravasations of blood are also met with (3) beneath the arachnoid and within the meshes of the pia mater, over areas perhaps small in extent longitudinally but more or less embracing the cord in one or more regions. The cord or nerve-roots may, however, be decidedly compressed by such hæmorrhages, even when they are small in amount, owing to the space into which the effusion takes place being comparatively shallow.

SYMPTOMS.—The symptoms of these affections are in a large proportion of cases vague and ill-defined. They may be much obscured by the causal conditions. In other cases they will vary in distinctness according to the amount and abruptness of the hæmorrhage.

As a rule the onset of symptoms is sudden. Pain in the region of the spine, in which the hæmorrhage exists, or radiating thence along the nerves emanating from this region, may be the first symptom. More rarely muscular twitchings or spasms may exist, either alone or with pains. These symptoms, dependent upon irritation and compression of sensory and motor nerve-roots, are at other times almost wholly absent. There may then be as abiding symptoms mere numbness or tingling in the parts affected, together with a sense of weight and paresis in the limbs. Actual paralysis is rare; and even when it is present the rectum and bladder mostly escape.

Where pain exists there is often stiffness of the spine; and these in combination greatly interfere with movement. Febrile reaction is usually absent or very slight. The severity of the symptoms may abate after a day or two, leaving only more or less paresis. In the case of large hæmorrhages, however, with extensive compression of the spinal cord, death may be rapid, occurring in the course of some hours or of a day or two.

The symptoms will vary as the effused blood presses upon the cord in the cervical, the dorsal, or the lumbar region. Where the effusion is in the cervical region in a traumatic case, in which there is obvious head-injury with a condition of stupor, it is almost certain not to be diagnosed. The patient is not sensible enough to complain of pain; and the irregular respiration and small disordered pulse, with slight tremor or rigidity of one or both upper extremities, may with more probability be ascribed to multiple head-lesions—as actually happened in a case which recently came under the writer's notice.

DIAGNOSIS.—It may be impossible to diagnose hæmorrhage into the spinal meninges in cases where it occurs as a concomitant of other grave diseases—

such as tetanus, eclampsia, or cerebral hæmorrhage; and also in cases where it merely complicates a traumatic injury of the spinal cord itself. In other cases the presence of certain causal conditions, together with the abrupt commencement of spinal symptoms in such combinations as have been above referred to, is sufficient to enable us to diagnose it from hæmorrhage into the substance of the cord, as well as from meningitis or acute softening (*see SPINAL CORD, Diseases of*). The gradual onset of the symptoms arising from tumours of the spinal cord, or of the spinal meninges, makes it more easy to separate these affections from meningeal hæmorrhages.

PROGNOSIS.—Spinal meningeal hæmorrhages are as a class decidedly less grave than meningeal tumours. They are unlike the latter, moreover, inasmuch as the worst symptoms attendant upon them are produced at once, instead of being only very slowly evolved; so that after a short time, unless the blood effused happen to have produced a certain amount of compression of the spinal cord, the symptoms gradually diminish in severity. Large extra-meningeal hæmorrhages compressing the cervical region of the cord are by far the most serious forms of this affection.

TREATMENT.—In the treatment of spinal meningeal hæmorrhage the patient must of course be kept perfectly quiet and in the recumbent position. Spoon-diet should be administered for a few days; and vascular sedatives, such as aconite, may be given with advantage. Some recommend active purgation and the abstraction of blood from the neighbourhood of the spinal column by cupping or leeches. These measures, however, are of questionable utility, and the former especially might easily do positive harm.

In certain cases, especially in the extra-meningeal form of the disease, a surgical operation for the removal of the compressing blood-clot may be advisable.

H. CHARLTON BASTIAN.

MENINGITIS, Epidemic Cerebro-Spinal.—

SYNON. : Cerebro-spinal Fever; the Black Sickness (popular, Dublin); Spotted Fever; Cerebral Typhus.

DEFINITION.—An acute febrile disease, characterised by sudden invasion with extreme nervous shock, vomiting, excessive pain referred to the back of the neck and spine, spasmodic contraction of muscles, hyperæsthesia, and frequently cutaneous eruptions.

Cerebro-spinal fever occurs both in epidemic and sporadic form. The identity of the sporadic with the epidemic disease has been firmly established by the discovery of the specific micro-organism which is common to both. It seems also well-nigh certain from bacteriological investigation that the disease of infants known as posterior basic meningitis, which is by no means uncommon as a sporadic manifestation, is identical with the sporadic cases of cerebro-spinal fever.

ÆTIOLOGY.—*Age.*—In its epidemic form cerebro-spinal fever is most commonly met with in children beyond the age of infancy, and in young adults; it seldom occurs after the age of thirty-five years and is rare after forty. Sporadic cases of cerebro-spinal fever, considered apart from posterior basic meningitis, are probably most common in the later half of childhood and in early adult life; but if posterior

basic meningitis be included, then sporadic cerebro-spinal fever is probably much commoner in infancy than at any other period of life.

Sex.—Among adults the disease is much more frequent in males than in females; robust males between the ages of fifteen and thirty are its chief victims; but among children it seems to attack both sexes equally.

PREDISPOSING CAUSES.—The epidemic form seems specially to affect young recruits in the army, as was the case in the French epidemics. In Dublin it was specially severe among the recruits of the Royal Irish Constabulary. Probably this special incidence is to some extent related to the conditions under which soldiers live, for the epidemic form of the disease has occurred also in prisons, workhouses, and other public institutions, where crowding and defective sanitation were probable factors.

Cerebro-spinal fever is widely distributed in the temperate zone. It prevails more in cold than in hot weather, and is far more frequent in winter and spring than at any other time of the year.

Excessive fatigue seems to increase the liability to the disease; it has arisen after a hard day's hunting, foot-racing, long walks, dancing, or in children exhausted from outdoor play.

MODE OF SPREAD.—In epidemics it occurs in isolated localities far apart from one another; it does not seem to extend from a district to adjacent districts. The method of communication is uncertain; direct contagion is very rare, if indeed it occurs. The specific micro-organism has been found by several observers in the nasal secretion, and it is possible that dried-up secretion on handkerchiefs or dried-up expectoration may serve in some instances to spread the disease. The occurrence of an epidemic disease with purpura and meningitis in horses, during the prevalence of epidemic cerebro-spinal fever in some places, suggests the possibility of infection from animals.

BACTERIOLOGY.—The specific micro-organism of this disease is the *Diplococcus intracellularis* which was first described by Weichselbaum. As its name implies, it is found chiefly within the cells of the exudate. It stains easily with methylene blue or any of the ordinary stains; it is decolorised by Gram's method. It is aerobic, and grows well on glycerin-agar or blood-serum. In cultures it seldom lives more than two or three days. It has, however, been observed by Jaeger and others that this is not invariably the case: it occasionally lives two or three weeks or even longer. Until recently this micro-organism was confused with the pneumococcus, from which it should be carefully distinguished. As in other forms of meningitis a mixed infection occasionally occurs, thus the pneumococcus, staphylococcus, or streptococcus has been found in some cases with the specific micro-organism (Councilman, Mallory, and Wright). The *Diplococcus intracellularis* has been found not only in the meningeal exudation and cerebro-spinal fluid, but also in the blood during life (Osler), in the pus which occasionally forms in the joints, and in the nasal discharge which is frequent at the onset of the disease. This last discovery suggests that the nose may be the channel of infection in some cases.

SYMPTOMS.—The onset is almost invariably acute. In the most severe cases the patient when apparently in vigorous health is suddenly attacked by faintness, vomiting, and intense pain referred especially to the back of the head and neck; the

extremities become cold; the patient becomes insensible and convulsed; the limbs are rigid. Maniacal delirium may be a marked feature at the onset, and in a later stage the patient may fall into a dull apathetic condition.

In many cases some coryza with nasal discharge is present at the onset, and there is frequently also slight conjunctivitis at this stage.

Pain in the head, back of neck, and along the spine, is generally severe; the head is drawn back so as to be almost at a right angle with the spine; the whole back is sometimes arched as in tetanus; the muscles become rigid, and the skin extremely sensitive; neuralgic pains are also complained of in all parts of the body.

Paralysis of one or more limbs is sometimes present, usually of hemiplegic distribution, and most frequently attacking the arm. Paralysis of cranial nerves is less frequent than in tubercular meningitis; the ocular muscles are most often affected, so that strabismus is present.

The tendon-jerks are very variable, being sometimes increased, sometimes diminished.

Cutaneous eruptions appear in many cases within the first twenty-four hours. Herpes is perhaps the most common, and is sometimes very extensive; it occurs especially on the face, neck, and shoulders. Herpetic eruptions are met with as frequently in mild as in severe cases. A purpuric rash is present in some cases, especially in the more severe, and has been a marked feature in some epidemics. It usually appears first on the legs, and may be confined to the lower extremities. The spots are usually black, raised, about a line in breadth, and feel like a small shot under the skin. Sometimes these raised spots are surrounded by a dark purplish areola; in other cases large purpuric patches many inches in extent form on various parts, and may even coalesce and cover the entire body. Erythematous rashes are seen in some cases, and pemphigoid bullæ sometimes appear in the advanced stages of the disease.

Vomiting may be more or less persistent throughout the illness; the bowels are usually costive. Examination of the optic discs usually reveals nothing abnormal beyond slight congestion; optic neuritis is uncommon: amaurosis without obvious cause, a common symptom in the posterior basic meningitis of infants, would seem to be rare in the cerebro-spinal fever of older children and adults. The pulse commonly shows increased frequency, but only occasionally is irregular. The blood shows some leucocytosis. The temperature in cases where there is much initial prostration may remain low; the respiration then becomes of a sighing character, the pulse rapid with a peculiar jerky beat, giving a sharp upstroke to a sphygmographic tracing, and after a day or two, or it may be only a few hours, the patient dies in a state of collapse. More often the temperature rises and there may be continuous pyrexia, so that the chart resembles that of typhoid fever for two or three weeks; in other cases the temperature is of a remittent or intermittent type.

COMPLICATIONS AND SEQUELÆ.—After the acute stage is past, a persistence of symptoms, especially of vomiting and headache, may be due to the occurrence of hydrocephalus, which may also produce coma and convulsions and eventually prove fatal.

Ocular complications are frequent: the eye may be attacked by a low form of inflammation terminating

in a purulent infiltration of the whole or part of the organ : the cornea is more frequently involved than any other portion ; this sometimes gives way and the whole contents of the globe escape, causing hopeless loss of the eye. The sight is often permanently impaired by iritis or opacity of the cornea. In many cases, however, the inflammation completely subsides. It is remarkable that it is the right eye which is usually attacked, that both eyes are seldom affected, and rarely the left eye alone.

Deafness is not very common, but has been met with in several cases, and is sometimes permanent. Acute inflammation of the larger joints—sometimes an actual arthritis, sometimes a peri-arthritis—is a frequent complication in some epidemics, and has been observed also in the sporadic cases ; this may lead to suppuration in the affected joint.

Hæmorrhages are frequent in the more malignant forms, and are almost always present in cases where the purpuric blotches are of large extent : these hæmorrhages have occurred from the nose, uterus, bowels, kidneys, and ears, in about the foregoing order of frequency. Gangrene is occasionally met with, and the cases in which it occurs are usually fatal, but toes have been lost, and yet the patient has recovered ; the purpuric patches have also sloughed without serious danger to the patient's life.

PROGNOSIS.—The prognosis of cerebro-spinal fever depends much upon the form the affection assumes, and for convenience it may be divided into the following groups : (1) Cases of a very mild form, terminating in recovery ; the duration being usually from one to three weeks. (2) Cases of a very severe form, setting in suddenly, with violent and well-marked symptoms, purpuric spots and blotches, a tendency to hæmorrhages, deep collapse and coma ; usually terminating fatally in from a few hours to three days. (3) Cases of medium severity where all the nervous symptoms set in with less suddenness than in the cases just mentioned, with no purpuric blotches usually, and no hæmorrhages. These usually yield to treatment, and terminate in recovery in from two to six weeks. (4) Cases which set in either in a mild or in a severe form, but in which on the subsidence of the fever the strength does not return, convalescence is retarded or arrested altogether, and the patient falls into a general atrophic condition and usually dies in from three to six months, of marasmus.

By deciding to which of the above groups the case belongs, the prognosis will be to a great extent determined. The chief indication of danger is the early appearance of purpuric and hæmorrhagic conditions ; the supervention of hydrocephalus also makes the prognosis very grave.

The mortality in cerebro-spinal fever is very high, probably about 60 per cent. There are not at present sufficient data to determine whether there is any marked difference in this respect between the sporadic and the epidemic cases. The mortality has varied considerably in different epidemics : in some of those which occurred in America, it is placed as high as 75 per cent. ; among the Irish Constabulary it reached 80 per cent. The mortality is highest at the beginning of epidemics.

DIAGNOSIS.—Cerebro-spinal fever is liable to be confounded with typhus fever on account of the petechial rash, but is distinguished from it by the eruption appearing suddenly without any previous mottling of the skin. The nervous symptoms also distinguish it from typhus, although in a case of

typhus complicated with meningitis the diagnosis may be impossible. It is distinguished from *purpura hæmorrhagica* by the intensity of the fever, and the localised nervous symptoms. The malignant cases are more likely to be mistaken for malignant scarlatina than for any other disease, and must be distinguished therefrom by the rash, sore-throat, and nervous affections ; yet in some cases the two diseases have been indistinguishable from each other, especially where death occurred within twenty-four hours, and both were epidemic at the time. In other cases malignant small-pox has been mistaken for this disease.

Lobar pneumonia with cerebral symptoms, and influenza with headache and pain in the back may simulate cerebro-spinal fever, but in the former the presence of the characteristic signs in the lungs or the marked rapidity of respiration may make the diagnosis clear, while the latter lacks both the rigidity and retraction of the head and also the rashes which characterise the meningeal affection.

A sign which is sometimes of value in the diagnosis of spinal meningitis, and which has been described especially in connection with the diagnosis of cerebro-spinal fever, is the reflex contraction of the flexor muscles at the back of the thigh which occurs when an attempt is made to extend the leg on the thigh, with the thigh at the same time flexed as in the sitting posture. See p. 820.

From other forms of meningitis cerebro-spinal fever is distinguished chiefly by its sudden onset and by the rashes which frequently accompany it. Unlike suppurative meningitis, cerebro-spinal fever shows no obvious focus of infection such as a primary lobar pneumonia, or an empyema, or disease of the ear, and it differs from tubercular meningitis not only in its acute onset and the presence of a rash, but also in the marked opisthotonos, which is usually lacking in the tubercular disease.

The use of lumbar puncture for diagnosis has been advocated recently, and may be advisable in some cases. The naked-eye appearances alone of the fluid withdrawn may be sufficient to determine the presence of meningitis, the nature of which is determined by bacteriological examination of the fluid. See LUMBAR PUNCTURE.

MORBID ANATOMY.—The skull and dura mater are often abnormally vascular ; the cerebral sinuses are much distended with blood. All the membranes of the brain are more or less congested ; the arachnoid especially is vascular and opaque from inflammatory exudation—this opacity varies from slight milkiness to thick and dense deposits.

The characteristic lesion is the whitish- or greenish-yellow fibrino-purulent deposit found at the base of the brain ; in many cases, however, it is not limited to the base but extends up along the sulci to the vertex.

This deposit varies somewhat with the duration of the disease : in cases which have lasted a week or two, it is abundant, yellowish or greenish ; and the origins of the nerves seem to be buried in and compressed by the exudation. The brain-substance itself is more vascular than normal, and there is some inflammatory infiltration of its superficial layers. The ventricles in the more acute cases contain turbid fluid, in the more prolonged they may be much distended by excess of clear cerebro-spinal fluid.

In the spinal cord the lesions are similar to those found in the brain and its membranes.

Purulent infiltration of the eyeball, and effusion into the joints are met with in some cases. The lungs sometimes show extreme congestion or actual broncho-pneumonia; the liver and spleen have been found congested and softened in many cases.

TREATMENT.—The treatment in the early stage must be directed to recovering the patient from the collapse. This is best done by the application of heat, the administration of small quantities of stimulants or stimulating enemata, and the application of sinapisms over the chest and back. In the next stage of the disease attention must be almost altogether directed to allaying the spinal irritation and promoting absorption of the exudation. The extreme irritation will be best diminished by the use of belladonna and bromide of potassium. Ergot has also been found useful for this purpose.

The pain, which is extreme, will yield best to frequent and considerable doses of opium; indeed many physicians have relied altogether on opium as the curative agent. Chloral hydrate has proved beneficial in conjunction with bromides, in allaying restlessness and procuring sleep. For promoting absorption of the exudation, mercury and iodide of potassium have been chiefly relied upon. In the more sthenic cases calomel may be employed with benefit in small and repeated doses. The disease being usually of an asthenic type mercury will seldom be well borne, and iodide of potassium should be preferred.

Leeches applied to the back of the neck, behind the ears, or to the temples produce great relief of the excessive pain in the head and upper part of the spine. The application of ice to the head and spine temporarily allays pain, but there is little evidence of permanent benefit being derived therefrom. In prolonged cases blisters applied along the spine have seemed to do good.

Recently the withdrawal of cerebro-spinal fluid by lumbar puncture has been used as a therapeutic measure; but it seems more than doubtful whether any permanent good is derived from it: probably the most that can be said in its favour is that some temporary improvement, lasting a few hours, has occasionally followed its use. Drainage with laminectomy has also been tried, and recovery after the operation has been recorded. This method of treatment may be 'justifiable in certain severe cases in which the spinal symptoms are very marked' (Osler). Local complications must be treated as they arise. Stimulants are required in considerable quantity in a large number of the cases which present adynamic symptoms.

G. F. STILL.

MENINGOCELE.—See SKULL, Diseases and Deformities of.

MENINGO-ENCEPHALITIS.—A name given to a pathological condition in which inflammation of the pia mater implicates the subjacent cortical substance. This condition probably always exists to a certain extent in meningitis, and reveals itself on careful microscopic examination—although the inflammatory changes may not have advanced far enough to produce an easily appreciable amount of softening.

MENINGO-MYELITIS is a term used to indicate a condition in which inflammation of the spinal meninges implicates the surface of the spinal cord. See MENINGO-ENCEPHALITIS.

MENOPAUSE (μηνῆς, the menses; and παῦσις, a cessation).—The natural cessation of the menstrual flow, or 'change of life,' in the female. See CHANGE OF LIFE.

MENORRHAGIA (μηνῆς, the menses; and ῥήγνυμι, I burst forth).—Over-abundant menstruation, whether due to excessive quantity or to undue frequency. See MENSTRUATION, Disorders of.

MENSTRUATION, Disorders of.—SYNON.: Fr. *Troubles de la Menstruation*; Ger. *Störungen des Monatsflusses*; *Störungen der Menstruation*.

For the due performance of menstruation two conditions are essential, namely, sound general health, and normally developed organs of generation. Disorders of the menstrual process may be brought about by very many conditions. These disorders are generally divided into: I. *Amenorrhœa*, where the discharge is absent, or deficient in quantity. II. *Dysmenorrhœa*, where the function is performed with difficulty and pain. III. *Menorrhagia*, where the discharge is profuse.

I. **AMENORRHŒA.**—SYNON.: F. *Aménorrhée*; Ger. *Amenorrhœ*.

ÆTIOLOGY AND SYMPTOMS.—Amenorrhœa is dependent either on *general* states; or on *local* pathological conditions—that is, on lesions of the uterus and ovaries.

(1) All conditions or influences which tend to deteriorate the blood, or which act unfavourably on nutrition, may be causes of amenorrhœa. The most common of these is the demand made on the system in the development of the aptitude for conception, the growth and separation of ova, and the performance of the menstrual function. At this time the breasts develop, the ovaries and uterus enlarge, the pelvis grows, and the whole form becomes altered. Many women who during childhood have enjoyed apparently perfect health, as they approach puberty become gradually or suddenly anæmic or chlorotic, without any assignable cause other than the demand made on nutrition by the process of development through which they at the time pass. Nutrition becomes impaired, tastes perverted, pains of a neuralgic character are felt in various parts of the body, the menstrual discharge does not appear, or it may appear once scantily and then at irregular intervals, or it may disappear for months or even years. All the symptoms of anæmia are present, and the patient is languid and listless, lacks energy, and is in more or less constant suffering. The above course of events may take place even in cases where the surroundings are favourable to healthy development. Hygienic conditions, however, play a most important part in the proper development of the female functions, and when the surroundings are unfavourable, evil is sure to follow. Want of food or improper food, want of fresh air or impure air, want of exercise, foul gases, malaria, are prolific causes of failure or imperfection in the growth and development of the young girl, and are common causes of amenorrhœa. Disease also is by no means an infrequent cause of the condition under consideration, such as phthisis, Bright's disease and diseases of the liver, stomach, and nervous system. Emotion, fright, or grief, change of air and food (as when girls go from the country to London), and cold, may arrest or suspend the monthly discharge.

(2) Amenorrhœa may be due to local conditions.

These are absence or disease of the ovaries, of the uterus, or of both; and imperfect development of one or both organs.

In cases where the ovaries are absent, the change in form, from girl to woman, which normally takes place at puberty, does not occur. The girl grows but does not develop. A masculine appearance supervenes, the breasts remain small, the pelvis narrow, the voice becomes manly and harsh, a beard may grow on the face, sexual passion is absent, and the health remains good.

When the uterus alone is wanting, there may be no indication of the condition in the state of the general health or development, and local examination is necessary in order to detect the circumstance. In these cases the vagina terminates in a *cul de sac*, and the uterus cannot be felt on examination. On introducing a finger into the rectum and a sound into the bladder, it is found that the two organs are in contact, and that there is no uterus between them. There are, however, as a rule, one or two small fibrous masses representing the uterus.

Certain diseases, such as tuberculosis and atrophy, involving the whole substance of the ovaries, and also atrophy of the womb, may cause amenorrhœa.

Amenorrhœa from Retention.—In these cases the sanguineous discharge is separated, but does not appear externally, owing to atresia of the genital canal. The closure may occur at any point between the os uteri and the vaginal orifice. A membrane may close the os tincæ; the hymen may be imperforate; the vagina may be absent, or its walls may be adherent at any part of its course, or along the whole of it. The occlusion may be congenital, or may arise from inflammation during childhood or after severe labour. In these cases the menstrual molimina are periodically present, but the catamenia do not appear. The molimina increase in severity from month to month; the patient has pain in the back and a sense of weight in the pelvis, and becomes pale and sallow; the abdomen after a time begins to enlarge, and continues to increase at monthly intervals. On examination a tumour having the shape of the enlarged uterus may be felt rising from the pelvis. It is smooth, elastic, and dull on percussion. If the condition be not discovered, the distension of the uterus may go on to rupture, or its contents may pass along the Fallopian tubes into the abdomen, causing peritonitis and death.

DIAGNOSIS.—Whenever a patient suffers from amenorrhœa, pregnancy should be thought of. If this state can be excluded, the general condition should be investigated. Anæmia and its causes should be sought for. The chest, heart, and urine should be examined. If there be no general condition to account for the amenorrhœa, the practitioner should see whether the breasts and pelvis are developed, and examine the vulva and vagina for obstruction, if there be any suspicion of such a condition. Finally, it may be necessary to examine the uterus and ovaries.

TREATMENT.—The treatment of the first form of amenorrhœa is the treatment of the general state. If there be want of constitutional vigour, change of air, exercise in the open air, mental occupation, but not severe, and nourishing diet should be advised. The stomach and bowels should be attended to; and gentle aperients and salines given if the tongue be foul; then vegetable tonics, iron, iodides, or

other appropriate remedies. No efforts should be made to act especially upon the uterus, and this is particularly binding when the amenorrhœa is dependent on phthisis, Bright's disease, or similar conditions.

The second form is often incurable. In those cases in which the uterus and ovaries are absent nothing can be done. If the uterus be present, but imperfectly developed, much may be done when the cases are seen early, but nothing if seen late. Attempts have been made to promote the growth and development of the uterus by local treatment, but without success. For this purpose stem-pessaries, galvanic pessaries, and irritants have been used, but with only injurious results. In these cases, whether they be seen early or late, local treatment is of no use, while general treatment, directed to improve the health and favour growth, may prove of the greatest value. Plenty of good plain food, walking-exercise short of fatigue, and freedom from school and hard mental work, are the means which favour the easy and early transition from girlhood to womanhood; while over-work, sedentary habits, deficient or bad food, and bad air produce a rich harvest of physical suffering peculiar to women.

In cases of retention of the menses from atresia of the genital canal, an outlet must be made for the flow. If the hymen be imperforate it should be divided, and the fluid allowed to run out. In cases of absence of the vagina, a canal has in some instances been successfully made. This, however, should only be done in cases in which the uterus and the ovaries are developed. In atresia of the os uteri the offending structure should be divided by the trocar or knife. These operations are accompanied by a considerable amount of danger. Patients not infrequently die after them from peritonitis or shock. It should not be forgotten, however, that it is imperative to remove the menstrual fluid retained, for unless this be accomplished death is inevitable.

II. Dysmenorrhœa.—**SYNON.** : Fr. *Dysménorrhée*; Ger. *Dysmenorrhœ*.

In dysmenorrhœa, menstruation is accompanied by pain—that is, pain referable to the genital organs. This pain is seated in the pelvis, and radiates to the sacrum, groins, and thighs. In some women the menstrual function is performed without pain or discomfort of any kind. As a rule, however, they suffer more or less from dull aching in the pelvis, backache, headache, languor, and lassitude during the catamenial flow. When the dull aching amounts to sharp pain, the function is performed abnormally, and the woman is said to suffer from dysmenorrhœa. This symptom is frequently met with, and in association with many pathological conditions of the pelvis; diseases of the uterus, such as fibroids; of the tubes, such as congestion and inflammation; of the ovaries; and also with general diseases, such as anæmia, gout, and rheumatism.

ÆTIOLOGY AND SYMPTOMS.—Dysmenorrhœa has been referred to five different conditions, upon one or more of which it is supposed to depend. Hence five kinds of dysmenorrhœa have been described: (1) *Mechanical or obstructive*; (2) *Conjunctive or inflammatory*; (3) *Ovarian*; (4) *Membranous*; and (5) *Spasmodic or neuralgic*.

I. Mechanical or obstructive dysmenorrhœa.—This form of dysmenorrhœa was long thought to be the most common; indeed, it has been asserted

that dysmenorrhœa cannot be said to exist without obstruction to the flow of blood from the uterus. Opinions, however, differ greatly with regard to the seat of the obstruction. Robert Barnes believed it to be seated usually at the os tincæ, and to be frequently accompanied by conical cervix; Marion Sims thought its most frequent seat was the os internum uteri; while Graily Hewitt referred the obstruction to flexion of the uterus in the great majority of cases—the obstruction being caused by the narrowing of the uterine canal at the point of flexion. The outer orifice of the uterus may be closed from birth, or in consequence of inflammation occurring subsequently, and thus cause obstruction to the escape of the catamenial fluid. There is no question therefore that this condition is one that may give rise in some way to painful menstruation. Such a narrowing of the os externum as to give rise to dysmenorrhœa is, however, extremely rare. A narrow, or so-called pin-hole, os generally admits the uterine sound, and women, subjects of this condition, frequently menstruate without pain. Indeed, it has been abundantly proved that pin-hole os plays no part in the production of dysmenorrhœa. The same may be said of contraction of the inner orifice. This part is rarely or never met with so small as to prevent the passage of the sound, and just as rarely presents obstruction to the escape of the fluid. Wherever the sound can be passed it may be safely inferred that there can be no obstructive dysmenorrhœa. That flexions of the uterus can interfere with the calibre of the canal and obstruct the menstrual flow is a simple theory, and all observations in the dead body go to show that it is fallacious, for the few flexed uteri which are found in our museums present patent canals. The only instances in which the canal is constricted by flexion are those in which senile atrophy has taken place—that is, when the walls of the organ have become thinned by age; but by this time the menopause has been passed, and dysmenorrhœa become impossible. So-called retroflexion of the uterus may, however, give rise to dysmenorrhœa when the body of the organ sinks into the pouch of Douglas, and it, together with the broad ligaments, becomes constricted by the sacro-uterine ligaments. Just as hernia of the uterus may give rise to congestion and dysmenorrhœa, so such a condition would prevent the return of the blood along the uterine veins, and lead to swelling and congestion of the body of the uterus, and painful menstruation.

2. *Congestive or inflammatory dysmenorrhœa.*—This name has been given to those cases of painful menstruation in which the uterus is enlarged and heavier than natural. It is met with in the married and in the single, but it is probable that it never occurs as a primary affection. Congestion and inflammation are frequent accompaniments of dysmenorrhœa when they are not the cause of it. They are generally the result of labour or abortion, or of dysmenorrhœa itself, of infection or mischievous meddling, more especially the use of instruments, such as the uterine sound. The symptoms are a continuous dull aching pain, chiefly in the sacrum and thighs, and a sense of weight and fulness in the pelvis. This form does not deserve the name of dysmenorrhœa, for the pain is at its worst at other times than during menstruation, and is frequently relieved by the appearance of the menstrual flow.

3. *Ovarian dysmenorrhœa.*—This does not deserve the name of dysmenorrhœa, for it is not due to menstruation—that is, to the discharge of the sanguineous fluid from the uterus, but to the growth and rupture of the Graafian follicles. The Graafian follicles develop gradually, and take a long time to arrive at maturity. It is not a sudden process. Towards the end of their growth, when they are about to rupture, the ovarian pain is experienced. They usually burst some time before the appearance of the menstrual flow, but the rupture may happen during the flow or after its cessation. Pain usually comes on before the flow—a few days or a week—and may cease with the appearance of the menses, or several days before that event; the suffering may, however, come on at any time during the flow or immediately after it has ceased, or at any time during the interval. It is situated usually in the left ovarian region, for the left ovary is more frequently affected than the right, the pain extending down to the thighs and to the sacro-iliac joint of the same side. Not infrequently the corresponding kidney is tender. Pain may occur in the right or left side at alternate periods—or a period may pass without pain. Vomiting and hysterical manifestations are often present. There is superficial and deep tenderness over the painful part. Patients often say that they have a swelling in the side, and, on examination, a diffused fulness is found in the ovarian region, which is tympanitic, and evidently due to local distension of intestine with gas. Examination *per vaginam* and *per rectum* will often detect a small body or swelling, tender and movable at first—later on fixed—on the affected side and a little behind the uterus. Pressure on the swelling calls forth severe pain and a feeling of sickness. At a later period the uterus becomes less movable and drawn to the affected side. This is, doubtless, due to contraction of inflammatory products, and not to distension of the broad ligaments, for it occurs in long-standing cases only. Micturition is frequent and painful. The pathological lesion is inflammation of the uterine appendages—the tubes, the ovaries, and the peritoneum, the Graafian follicles, the stroma, or the surface of the ovaries, one or all may be affected. This condition is again rarely primary. In women who have had children it is often due to parturition and abortion. In the unmarried, it is often the result of long-standing dysmenorrhœa, sometimes of acute specific disease, or of inflammatory mischief set up by causes mentioned in the preceding paragraph, or exposure to cold during menstruation. Gonorrhœa is also a cause.

4. *Membranous dysmenorrhœa.*—In this form a membranous sac, having the shape of the body of the uterus, is expelled with the menses. The sac has three orifices corresponding to the orifices of the Fallopian tubes and the inner orifice of the uterus. It has an internal smooth, punctated, and an external flocculent surface. Occasionally during expulsion the sac is turned inside out. It may be passed with every or every other menstruation, or only occasionally. Instead of being passed in the form of a complete sac, the membrane may be broken up and expelled as shreds of various sizes. Microscopical examination shows that the membrane possesses a structure identical with the lining of the body of the uterus. It contains glands and blood-vessels, and is, in fact, the decidua menstrualis. It has been said that this membrane is always the result of

conception, but ample evidence has been published in refutation of this statement. Other bodies may be expelled from the uterus during menstruation, such as clots of blood, fibrin, masses of mucus forming casts of the uterine canal, casts of the vagina, and products of conception. Several cases of monthly abortion have been recorded. These substances can be distinguished from the decidua menstrualis by microscopical examination only, and easily, except the products of conception. These present the structure of the decidua; but they also present some additional appearances which, if found, are characteristic, such as the sac—partial or complete—formed by the decidua reflexa and the large cells which are met with in the decidua vera and chorionic villi. When cases of this disorder come under notice the uterus is, as a rule, enlarged. This, however, is not always the case. The enlargement is probably a condition secondary to the dysmenorrhœa or to previous gestation. There is commonly tenderness of the pelvic tissues around the uterus, probably of the peritoneum. Ovaritis is frequently present. These conditions are probably secondary. Affections of other mucous membranes may be present, such as bronchial catarrh. Membranes may be passed from the uterus without pain; or pain may be present, but varying in degree from slight discomfort to intense suffering. The severest pains, however, are not due to obstruction caused by the passage of the membranes blocking the os uteri and causing retention of the fluid, but to spasm of the uterus. The passage of the membrane takes place often on the third day of menstruation, but it may occur later. Frequently shreds are passed from the first or second day to the end of the flow. With the expulsion of the membrane there is usually a gush of blood, after which the flow proceeds normally. The catamenial discharge may be normal in amount, considerably increased, or even scanty.

The pathology of this affection is somewhat obscure. Several views have been held with regard to it, some of which deserve no notice. Inflammation, however, is so frequent an accompaniment, that the view that inflammation is its cause is one which deserves attention. Against this view is the fact that about two-thirds or three-fourths of the cases are cases of primary dysmenorrhœa, in which inflammation could not have been present; and it is consequently inferred that the inflammation, which is so often present, is really a secondary development, being the result of the dysmenorrhœa; moreover, on no other surface of the body is inflammation known to give rise to a periodical exudation of this kind, or to change the character of the mucous surface in such a manner as to cause it to be shed in the way the mucous membrane of the uterus is shed in this disease. The cause is probably to be sought in malnutrition of the uterus, which in some cases has existed *ab initio*, while in others it has succeeded to some disease, such as inflammation or imperfect involution of the uterus after pregnancy. It has been met with also in gouty and rheumatic subjects, but it is not known if it holds any relation to these diseases. The pathology of the affection appears to be a failure of the molecular disintegration of the decidua menstrualis which takes place during normal menstruation, and this must be due to the presence in the decidua of some tissue which resists disintegration more than the healthy tissues of that membrane. The only tissue which has been found in the uterine wall which would offer

such resistance to disintegration is fibrous tissue. It is known that this varies somewhat in quantity in the wall of the uterus, according as it is diseased or healthy. In cases of inflammation of the uterus in which imperfect resolution has taken place, excess of fibrous tissue is found in the wall. In cases of sub-involution a similar excess is found, and it would be expected that in cases of imperfect development at puberty a similar excess would be found. It is known that the organs in which membranous dysmenorrhœa is met with are imperfectly developed uteri, uteri that have been inflamed, and uteri that have been pregnant and in which parturition or abortion has been followed by an imperfect return of the organ to its natural state; and it is maintained that the presence of an excess of fibrous tissue in the wall of such uteri is the cause of the shedding of the decidua as a membrane. This is the most probable explanation of the occurrence of membranous dysmenorrhœa.

5. *Spasmodic or neuralgic dysmenorrhœa*.—This form of dysmenorrhœa includes the very great majority of severe cases. For a time spasm or neuralgia were regarded as an asylum for ignorance, and other conditions which formed the basis of the mechanical theory of uterine pathology were put forward in their place. Further research, however, has shown that spasm and neuralgia are by no means conditions of no importance in dysmenorrhœa, that the foundations of the mechanical system were laid in error, and that dysmenorrhœa is but another name for uterine colic. It is well known that with dysmenorrhœa, flexions of the uterus, a narrow external orifice, or a narrow internal orifice may be present, and it is equally well established that these conditions may be removed and yet the dysmenorrhœa remain. The inner and outer orifices may be incised, and the flexion straightened, without relief. The observations of Vedeler and Herman prove that the percentage of virgins who suffer from dysmenorrhœa is almost the same whether the uterus be straight or in a state of flexion. In fact, dysmenorrhœa is just as frequent in the absence of flexion of the uterus as when flexion is present; and every practitioner who has seen a considerable number of cases of dysmenorrhœa has ample proof that a narrow external or internal os is not a common cause of it.

Dysmenorrhœa may be divided into two categories—the primary and the acquired. Primary dysmenorrhœa is present from the commencement of menstruation, or soon afterwards. Acquired dysmenorrhœa comes on at a later period of life, after menstruation has been thoroughly established, often after pregnancy, labour, abortion, and in consequence of chills, inflammatory attacks of the pelvic organs, acute diseases, anæmia, and exhaustion. The primary variety forms the majority of cases, and in these no recognisable disease of the uterus is present. It is generally believed that the uterus undergoes regular contractions during menstruation. These cannot be observed in the healthy organ, but they have been witnessed in cases in which the uterus was enlarged by fibroid tumours. In health these contractions are painless. When they become irregular they are painful, and give rise to dysmenorrhœa. The pain is situated in the pelvis, and is referred to the uterus. It is of varying intensity: it may be slight; or it may be extremely severe—agonising. It radiates to the groins, sacrum, and thighs. It is often said to be all round the pelvis or lower part of the trunk, and is often com-

pared with the pain of labour, or that of abortion. The pain may come on a little before, with, or a little after the appearance of the discharge. Usually it occurs during the first twelve or twenty-four hours, and lasts from four or five hours to twenty-four, or even to the end of the flow. It is paroxysmal. There is often tenderness of the skin of the hypogastrium and groins, vomiting, hiccup, headache, hysteria; and even delirium may be present. The menstrual flow may be scanty or profuse. In the former case it is often followed by an abundant yellow discharge lasting for a few days. There may be leucorrhœa throughout the inter-menstrual interval. Micturition is sometimes frequent and painful. Patients who suffer in this way may enjoy good health during the inter-menstrual interval, but often they suffer from neuralgic pains at other times than at the periods, and they frequently suffer from severe headaches at the time of their period.

TREATMENT.—Dysmenorrhœa is generally obstinate under treatment, and its course is very protracted. In many cases much may be done by attention to the general health, to the state of the stomach, liver, and bowels. During an attack, if severe, rest in bed should be enjoined, and hot baths. As drugs, solution of acetate of ammonium, antipyrine, and phenacetin are useful; sometimes opium and morphine are called for, for the relief of the pain. Alcohol in small doses is useless, and in large quantities intoxicates. During the interval saline aperients, iron, arsenic, bismuth, iodide of potassium, and ergot are of service; guaiacum resin alone or in combination with sulphur is sometimes of use. If there be a gouty or rheumatic tendency, this should be treated. As a rule, in these cases there is nothing to be gained by local treatment of so-called misplacement and conical cervix. Occasionally, however, in cases of severe retroversion or retroflexion, where the fundus of the uterus is grasped in Douglas's pouch, a pessary may be of use. Incision of the external orifice, in so far as the writer knows, is of no use. Relief sometimes follows incision of the internal orifice. Whether this relief is due to the enlargement of the canal caused by the incision, or to the stretching of the neck of the womb, which is generally carried out along with it, either by the introduction of a plug of lint or of a stem-pessary, is still a debated question. The idea of incising the neck of the womb, whether at the external or internal orifice, is based upon an error in pathology, namely, that the pain is due to mechanical obstruction to the flow of the menstrual discharge from the uterus; and, as it is a dangerous, and may be even a fatal proceeding, it should not be undertaken. Dilatation of the cervix, however, is the most efficient means we have for the relief of severe dysmenorrhœa when drugs and other treatment fail. The object of this procedure is not to enlarge the canal for the passage of the menstrual fluid, but to stretch the neck of the womb in order to destroy the tendency to spasm. Indeed, it is done on precisely the same principle as dilatation of the vaginal orifice is done for vaginismus, and of the sphincter ani in cases of spasm of that muscle. The dilatation may be effected by the use of tents made of *Laminaria digitata*, tupelo wood, or sponge; the first two are preferable to the last. They should be allowed to remain in the cervix for from six to ten hours, until the canal has been well dilated. Or, preferably, the dilatation may be carried out by means of bougies;

metallic bougies are the best, graduated according to English measurement. The dilatation may be carried out at one sitting, when the patient is anæsthetised, and a series of bougies from No. 6 or 8 to No. 16 to 18 passed; or at several sittings, when one or two bougies should be passed every second or third day, until the required size has been reached. Hegar's bougies are often used for this purpose, but the English metallic bougies are in every respect preferable. Dilators have been used for this purpose also, such as Priestley's or Ellinger's. Some of these have three blades and some have two. Some are opened by a screw and some by hand pressure. There are many instances in which these instruments have lacerated the cervix severely, and, their use being accompanied by greater risk than that of bougies, they should be avoided. Dilatation cures some cases and relieves others, but in a large number it proves of no use whatever.

III. Menorrhagia and Metrorrhagia.—**SYNON.**: Vulg. Flooding; Fr. *Ménorrhagie*; *Mérorrhagie*; Ger. *Mutterblutfluss*.

Menorrhagia is used to denote profuse menstruation; metrorrhagia, hæmorrhage from the uterus at any other time than the catamenial epoch. The two symptoms are frequently met with. Menorrhagia often exists alone. When metrorrhagia is present during menstrual life, the catamenia are, as a rule, also profuse. These hæmorrhages may be called forth by many lesions. Indeed, they may accompany the majority of the pathological conditions to which the pelvic organs are liable. They may also arise from general states—as scurvy, the hæmorrhagic diathesis, Bright's disease, phthisis, cirrhosis of the liver, and the acute specific diseases. The most common cases are, however, associated with distinct alterations of structure in the pelvic organs, as sub-involution of the uterus, polypus, fibroid tumour, cancer, displacements, retained portions of placenta, moles (fleshy or vesicular), fungous degeneration of the mucous membrane of the uterus, mucous polypi, ulcerations of the cervix, hæmatocele, inversion of the uterus, and congestion of this organ due to obstruction to the circulation through the heart and lungs or liver.

Profuse hæmorrhages of an irregular character occur also in young girls before the advent of regular menstruation. This form of uterine hæmorrhage is not common, but it is sometimes of very serious import, and occasionally has proved fatal. More frequent is the occurrence of irregular bleeding from the uterus at the menopause. The causes of these climacteric hæmorrhages are really not known. They have been said to be due to congestion, but on insufficient evidence.

TREATMENT.—The treatment of hæmorrhage from the uterus resolves itself into the immediate treatment of the attack, and the treatment of the condition leading to it. The treatment of the attack, or the means of arresting the bleeding, consists in great part in securing absolute rest. The patient should remain in bed in the recumbent position, and avoid all exertion—mental and physical. At the same time, internal remedies which tend to check hæmorrhage should be given. Of these, those most commonly used are ergot, hamamelis, hydrastis, gallic acid, the mineral acids, and acetate of lead. Mineral acids, in combination with sulphate of magnesium or sodium, often act well. Should acetate of lead be administered, the patient should be carefully watched, as some persons are

very sensitive to the action of the drug, and manifest symptoms of acute lead-poisoning after the administration of a small quantity. Should these means fail, recourse should be had to plugging the vagina or uterus. The vagina is plugged in the following manner: The patient is placed on her left side, a speculum is introduced, and the vaginal canal is firmly packed with pledgets of iodoform- or salalembroth wool or gauze, tied on a string for convenience of removal. This will arrest the hæmorrhage for a time, but it can only prove a temporary expedient. The plug is liable to become offensive, from decomposition of blood and of the secretions in the vagina, and should consequently be changed in forty-eight to sixty hours, or sooner. A more efficient means of arresting hæmorrhage is plugging the uterus itself. This is done by means of tents of sponge or laminaria, and with a twofold object. The first object is the immediate arrest of the bleeding; but the chief object usually is to dilate the canal of the uterus, so as to permit its exploration by the finger, and the discovery of the cause of the bleeding. This means will not only check the bleeding temporarily, but will in many cases effect a permanent cure. Tents should be rendered aseptic by immersion for some days in a solution of corrosive sublimate in absolute alcohol (1 in 1,000). To facilitate the introduction of a tent, a Sims's speculum should be used, and the cervix of the uterus should be fixed by a sharp hook. In many cases, however, tents will not be necessary. The hæmorrhage will be controlled by the other means enumerated, or the cause of the hæmorrhage will be made out without the use of tents. In all cases, however, in which the hæmorrhage is uncontrollable, or so profuse as to threaten life, or in which the cause of the bleeding is obscure, tents should be had recourse to, both to check the flow and complete the diagnosis. When the cause has been discovered, it should, if possible, be removed. Rapid dilatation of the unimpregnated uterus by means of bougies, so as to allow exploration of the cavity with the finger, is dangerous owing to the laceration of the cervix caused by them. When, however, a tent has been previously used dilatation by bougies is easy and with care safe.

But even after the uterine canal has been dilated, no definite cause may be found for the bleeding. In these cases, styptics, or even caustics, may be applied to the inner surface of the organ. Those chiefly used are a solution of iodine, a solution of perchloride of iron, chromic acid, carbolic acid, and fuming nitric acid. These are best applied through a uterine speculum of platinum or vulcanite, on a probe of similar material. While using these means, it should be borne in mind that internal uterine medication is not free from grave danger.

The rest of the treatment of menorrhagia consists in attention to the general health.

JOHN WILLIAMS.

MENSURATION (*mensura*, a measure).—A synonym for measurement. See PHYSICAL EXAMINATION.

MENTAL DISORDERS.—See INSANITY.

MENTONE, France, on the extreme East of the French Riviera.—A moderately warm, bracing, sheltered, and dry winter climate. Mean temperature in winter 52° F.; rainfall 24 inches. See CLIMATE, Treatment of Disease by.

MERCURY, Diseases arising from.—
SYNON.: Fr. *Hydragryrie*; *Intoxication mercurielle*; Ger. *Quecksilbervergiftung*.

Though considerable discrepancies of opinion have existed as to the poisonous or innocent properties of the metal mercury itself when swallowed, there can be no doubt as to the poisonous character of its soluble and volatile compounds, nor even as to the insidious nature of the vapours of metallic mercury. Metallic mercury has occasionally been administered in enormous quantities without producing any decided physiological effects; while, in other instances, salivation and other specific effects have resulted. These differences are doubtless due to the fact that, in those cases where effects have resulted from the administration, oxidation and solution of a portion of the metal had taken place. See OCCUPATION-DISEASES.

Mercurial poisoning may be either (A) *acute*, or (B) *chronic*; the former resulting from the administration of one or several large doses at short intervals, the latter form of mercurialism arising from the repeated exhibition of small doses of the less active preparations of the metal. There is also a peculiar form of mercurialism which is the effect of the inhalation of the vapours either of the metal or of its volatile compounds, and is characterised by paralysis.

A. Acute mercurial poisoning.—**DESCRIPTION.**—The effects produced by a considerable dose, say 60 grains, of one of the more soluble compounds of mercury, such as corrosive sublimate or the nitrate, are those of a corrosive and irritant poison. The effects are immediate. In the act of swallowing, an intense burning sensation is experienced in the mouth and throat, followed by excruciating pain in the stomach, and extending over the abdomen. The local effects of the poison are frequently visible, as a whitening of the tongue and fauces. There is vomiting, tenesmus, and purging, often of a bloody character. Colic, and great tenderness and swelling of the abdomen, are also symptomatic. Not infrequently there is suppression of the urine. The gustatory sensation is perverted; there is dryness of the mouth; and a brassy or metallic taste is generally experienced after the first local corrosive action of the poison has somewhat abated. The countenance is anxious; the skin is pale, cold, and clammy; and the pulse is small, weak, and rapid. The urine is blood-stained, scanty, or suppressed. Salivation may supervene, accompanied by fetor of the breath. Should recovery not take place, death may occur within a few hours, or may be delayed for one or more days; or the patient may more rarely succumb to some of the ordinary sequelæ of corrosive poisoning. When death supervenes speedily after the administration of the poison, the fatal result is usually due to collapse.

Most of the effects of acute mercurial poisoning may result from the application of a concentrated solution of corrosive sublimate or mercuric nitrate to the unbroken skin.

ANATOMICAL CHARACTERS.—The *post-mortem* appearances seen after acute mercurial poisoning are inflammation and even erosion of the mucous membrane of the stomach, and extravasation of blood beneath this membrane. Ulceration is rare. The intestinal tract also exhibits signs of extensive inflammation, and this has been noticed especially in the large intestine. The rectum is usually much inflamed, and its surface covered with shreds of

bloody mucus. A peculiar slaty appearance of the mucous membrane of the stomach and intestines, where not highly inflamed, has been thought to be characteristic of poisoning by corrosive sublimate.

DIAGNOSIS.—Though the symptoms of poisoning by corrosive sublimate, and other corrosive preparations of mercury, greatly resemble those produced by arsenic, the diagnosis is generally not difficult. The effects following almost immediately on administration, the metallic taste in the mouth, and the greater frequency of bloody stools in mercurial poisoning, serve to differentiate between the poisons. Where doubt exists, an analysis of the secretions may be made; arsenic is most readily detected in the urine, and mercury in the saliva. The existence of salivation and fœtor of the breath—though not always present—may also be valuable aids in completing the diagnosis.

TREATMENT.—In acute poisoning by corrosive sublimate, the best antidote is albumen, or the albuminoids in any soluble form. The white of one or more eggs should be beaten up with water, and swallowed as quickly as possible. Failing an egg, flour made into a thin paste may be administered. Albumen combines directly with corrosive sublimate to form an insoluble compound. On account of the powerful local action of the poison on the stomach, the use of the stomach-pump is not advisable; but if the vomiting be not free, emetics of as simple a character as possible may be administered. The rest of the treatment consists in alleviating pain by means of opiates, and the general treatment applicable for irritant poisons. Thirst must be alleviated by demulcent drinks. For this purpose milk, mixed with once or twice its bulk of lime-water, is excellent; the casein of the milk and the lime both tending to render the mercury insoluble, and so to act as antidotes.

B. Chronic mercurial poisoning.—**SYNON.:** Mercurialism.

DESCRIPTION.—The repeated ingestion of small doses of the more soluble and active preparations of mercury, such as the perchloride and the cyanide, may give rise to chronic symptoms; but these more frequently result from the administration of one or more doses of the more insoluble preparations of the metal, such as calomel or the oxides. When chronic symptoms follow the administration of one dose of a mercurial preparation, this is not altogether due to the peculiar idiosyncrasy of the patient, but is attributable in no small degree to the slowness with which mercury is eliminated from the system. There appears also to be a remarkable difference, not altogether dependent upon their differing solubilities, between *mercuric* or per-salts and *mercurous* or proto-salts, in respect to their toxic properties. Mercuric compounds are greatly more potent than mercurous salts. By far the most common result of the continued administration of mercury compounds is salivation. This consists in a profuse discharge from the salivary glands; swelling and tenderness of the gums; and fœtor of the breath. In children, and more rarely in adults, salivation may pass into sloughing and gangrene of the cheeks; and a fatal result may ensue. Other symptoms are nausea, colicky pains, depression, and those nervous symptoms to which the term 'mercurial palsy' has been applied; but this last group of symptoms, which is most commonly met with after inhalation of the vapours of mercury, must be described more in detail.

Mercurial Paralysis.—Workers in mercury, such as water-gilders, looking-glass makers, and the makers of barometers and thermometers, are apt to suffer from a peculiar form of shaking palsy, known either as 'the trembles,' mercurial tremors or metallic tremors, and, by the French, as *tremblement métallique*. This disease affects those who handle the oxides of the metal, but more frequently those who are exposed to mercurial fumes. Mercury exhibits a small vapour-tension, and consequently is vaporisable at all ordinary temperatures, but the tension of its vapour below 60° F. is very small. The metallic tremors may come on suddenly or gradually, and they may be unaccompanied by salivation. The upper limbs are first affected, and then by degrees the whole muscular system. The patient is affected with tremors when an endeavour is made to exercise the muscles, so that he is unable to guide, for instance, a glass of water steadily to his lips; he cannot put his feet steadily to the ground; and when he tries to walk he breaks into a dancing trot. The muscles of mastication and deglutition are affected in advanced cases. Delirium and mania have occasionally followed the continued inhalation of mercurial fumes. See OCCUPATION-DISEASES.

DIAGNOSIS.—The diagnosis of mercurial tremors is usually not difficult. It must be admitted, however, that in some cases the tremors produced by mercury are in no way distinguishable from those due to the now well-recognised disease known as disseminated, multiple, or insular sclerosis. The former are less readily confounded with ordinary shaking palsy (paralysis agitans) and the convulsive movements of chorea. The history of exposure to mercury will seldom be absent. In paralysis agitans the tremors are finer, and occur when the patient is at rest; and the peculiar forward gait, as if the patient were endeavouring to pass from a walking to a running pace, is characteristic. The metallic tremors come on only when the muscles are exerted, and usually they entirely cease when the patient is lying at rest or is asleep. The same may be said of the tremors of disseminated sclerosis; but here we have the peculiar consensual rotation of the eyes known as nystagmus. In paralysis agitans, when told to raise the affected hand, or to protrude the tongue, the patient performs both actions steadily. In mercurial tremors, and in disseminated sclerosis, the case is different—the tongue when voluntarily protruded is tremulous, and the patient cannot raise his hand, when requested to do so, without shaking. In both mercurial tremors and the tremors of insular sclerosis the muscular agitation ceases for the most part during sleep. In one form of metallic tremors the movements approach in character the convulsive movements of chorea.

TREATMENT.—In chronic mercurial poisoning it is obvious that the patient must at once be removed from the further influence of the metal. Masks worn over the mouth are not of much use. In mercurial tremors cessation from working with the metal and mild tonics of iron usually suffice for the speedy restoration to health; but the tremors occasionally persist throughout life. For salivation and the more formidable gangrene of the mouth, besides cessation of the administration of the metal, and the exhibition of tonics, potassium iodide may be given. Astringent gargles and active local treatment may perhaps be necessary.

THOMAS STEVENSON.

MESENTERIC CYSTS. — See ABDOMINAL CYSTS.

MESENTERIC GLANDS, Diseases of.—

1. Acute Congestion and Inflammation.—These glands are liable to become congested or inflamed in connection with any inflammatory condition affecting the intestinal canal. The situation and number of glands implicated will correspond mainly with the portion of bowel involved. They become enlarged, but the changes are seldom such as to give rise to any evident symptoms, and they subside as the cause of the irritation ceases to operate. When infected with pyogenic cocci, suppuration may supervene and fatal peritonitis follow.

In this connection allusion may be made to the special implication of the glands in typhoid fever and dysentery. The nature of the changes which they exhibit is described in the articles on these diseases, and the glands affected correspond to the portions of intestine involved. They do not always return subsequently to their normal condition, but may remain permanently atrophied or otherwise changed. In exceptional instances the glands in typhoid fever have suppurated or sloughed in their interior, giving rise to symptoms simulating perforation of the intestine, and they have even ruptured into the peritoneum, thus causing fatal peritonitis. See DYSENTERY; and TYPHOID FEVER.

2. Tubercular Disease.—Tubes Mesenterica.—Tuberculosis of the mesenteric glands constitutes a most important disease in children and young persons, and its occurrence has been attributed specially to the consumption of milk obtained from cows with tuberculous udders. It may be associated with tubercular ulceration of the intestines, to which it is then probably secondary, or exist independently of it, especially in children. It is frequently followed by tubercular peritonitis. The disease may be accompanied or preceded by phthisis, although this is comparatively rare in children, and the lung-affection is often secondary in these subjects. In adults, on the other hand, tubercular disease of the glands, when it does occur, is, in the large majority of cases, a complication of phthisis, intestinal ulceration, due to infection by swallowed sputum, being present at the same time.

The changes in the glands are similar to those characteristic of tuberculosis elsewhere in the lymphatic glands, namely, an increase in the number of cells, followed by degeneration and caseation, and ultimately by calcification should the case last sufficiently long; and it is usual in fatal instances to find these conditions associated in different glands. Tubercle-bacilli are present in more or less abundance. Should recovery take place all the involved glands may be converted into inert chalky masses, in which condition they remain for an indefinite time. In other cases the fibrous reticulum may be much increased. A case came under the writer's notice many years ago in which, the patient having died from an independent acute illness, the mesenteric glands were found to be universally calcified, this being associated with scarring of the external glands and other signs of old tubercular disease, from which the patient had quite recovered. The individual glands in mesenteric disease may attain a considerable size, and when they are agglomerated into a mass a distinct tumour is formed.

SYMPTOMS.—The symptoms due to tubercular disease of the mesenteric glands are often combined with, and masked by, those resulting from intestinal ulceration, tubercular peritonitis, pulmonary tuberculosis, or disease of other structures. The digestive organs are usually disordered, and, even if there should not be intestinal ulceration, children who suffer from mesenteric disease are very liable to enteric catarrh. Hence diarrhoea, with unhealthy stools, is a common symptom, which it is often difficult to check or to prevent. In other cases the bowels are constipated. Tuberculous mesenteric glands do not seem to be painful in themselves, but colicky pains in connection with the bowels are of frequent occurrence, and the disease of the glands may have some influence in exciting such pains. The abdomen is almost always distended and prominent, owing to the accumulation of flatus, and it may be markedly tympanitic. Hence, even when the glands are much enlarged it is often impossible to feel them, but they may sometimes be made out by deep pressure with the fingers over the corresponding part of the abdomen. In some instances this region is retracted, and then the glands may be more readily felt. Signs of fluid in the peritoneum, or of chronic tubercular peritonitis, may be present.

The general symptoms in *tabes mesenterica* are usually very prominent, as evidenced by wasting, which may reach extreme emaciation, anæmia, debility, and pyrexia, marked hectic fever ultimately supervening in some cases. Cases in which mesenteric glands are the seat of tubercular disease differ much in their severity; and the symptoms may be so indefinite that it is impossible to make any positive diagnosis of its existence. A large number of cases prove fatal; but it must be remembered that even after severe symptoms recovery may take place, the glands becoming calcareous and inert. When the glandular affection is secondary to pulmonary phthisis, the outlook is very bad.

DIAGNOSIS.—Two facts must be borne in mind. In the first place enlarged mesenteric glands rarely form a mass big enough to be called an 'abdominal tumour;' and in the second place, in the absence of small palpable nodules, and indications of tuberculosis elsewhere, the diagnosis must always remain doubtful. Tuberculous mesenteric glands without any other form of tuberculosis in thorax or abdomen are very rare; whereas wasting with flatulent distension of the abdomen in infants and young children is very common and readily amenable to treatment.

TREATMENT.—This mainly consists in the treatment required for tubercular disease in general, such as the administration of cod-liver oil, preparations of iron, quinine, and other tonics; favourable hygienic conditions and surroundings; change of air, especially to the country or to the seaside; and other appropriate measures. The diet needs particularly careful attention. It should be nutritious and digestible, but has often to be modified so as to render it suitable for the condition of the alimentary canal. Remedies directed to the improvement of the state of this canal, or to the relief of symptoms connected with it, are also often required. Guaiacol may be of service in some cases. The application of Ung. Hydrarg. to the skin of the abdomen is sometimes followed by recovery as in the case of tubercular peritonitis. Dry heat, fomentations, or poultices in connection with the

abdomen may be applied, should occasion call for them. *See* PERITONEUM, Diseases of.

3. **Hypertrophy.**—It will suffice to remark under this head that the lacteal glands are liable to be more or less hypertrophied in cases of lymphadenoma, and in the form of leucocythæmia attended by glandular enlargement. *See* LEUCOCYTHÆMIA; and LYMPHADENOMA.

4. **Atrophy and Degeneration.**—The mesenteric glands atrophy in old age, and they may also become wasted and withered after previous disease, such as typhoid fever.

5. **Morbid Formations.**—*Cancer* is chiefly met with as a secondary formation, the lacteal glands being particularly liable to become affected if the intestine is the seat of malignant disease. A considerable tumour may be formed, firm and nodulated; or the glands may remain separate. Physical examination may reveal the presence of the disease. Further, localised pain, with symptoms due to pressure, should it exist, together with evidence of a cancerous cachexia, and of the implication of other organs, especially of the intestines, constitute the clinical phenomena to be found associated with malignant disease of the lacteal glands.

FREDERICK T. ROBERTS.

MESENTERY, Diseases of.—*See* PERITONEUM, Diseases of.

MESMERISM.—**DEFINITION.**—The name of the process by which, rather more than a century ago, Anthony Mesmer, the deluded (or at all events the deluding) promulgator of the doctrine of 'animal magnetism,' induced the so-called mesmeric trance or sleep. *See* MAGNETISM, ANIMAL.

This mesmeric trance is identical with the condition now known as 'induced somnambulism,' or still more commonly as 'hypnotism' or the 'hypnotic state.'

The induction of the hypnotic state or sleep has hitherto been possible in only a certain, but variable, percentage of the persons with whom trial has been made, though a successful result has been much more frequent with women than with men. According to Richet, however, the operator should not be discouraged by the failure of his first attempts with the same person; as persons may succumb on the fourth or fifth trial, and subsequently prove thoroughly good subjects for experimentation. Persons who have once been hypnotised can in general be again brought with comparative ease into the same condition, and the facility of hypnotising such persons goes on increasing after each operation, owing to the existence of a predisposing mental state. A condition of excited expectancy is indeed a decidedly favouring mental state, though one which is not essential, since, according to Braid, Heidenhain, and others, even male adults who have heard nothing on the subject, and do not know for what purpose they are being experimented with, can often be hypnotised.

In persons who are favourably disposed for passing into the hypnotic state, the condition is easily induced by weak, long-continued, and uniform stimulation of the nerves either of sight, of touch, or of hearing. This state is, on the contrary, almost always easily capable of being abruptly terminated by some strong or suddenly varying stimulation of the same nerves.

Many of the lower animals, such as frogs and

fowls, can be thrown into an extremely similar condition as a result of certain sudden and powerful sensorial impressions. Preyer distinguishes the state into which they are thrown by a different name, namely, 'cataplexy,' because the mode or physiological process by which it is induced seems to be different from that by which hypnotism is caused.

The hypnotic state or sleep is one which varies much in intensity in different persons, and in the same person at different times. The principal phenomena that are exhibited or which can be detected in hypnotised persons are the following: (1) imitative movements; (2) exaltations of special sense; (3) illusions and hallucinations; (4) analgesia, general or unilateral, or even a condition of hemianæsthesia, general and special; (5) increased reflex irritability and tonic spasms of the voluntary muscles; and (6) other miscellaneous phenomena, such as spasm of the accommodative apparatus in the eye, dilatation of the pupils, increased rapidity of respiration and of the pulse, together with profuse perspiration.

According to Charcot, when hypnotism occurs in hysterical subjects more especially, it is divisible into three states, definitely related to one another, though not always occurring in the same order. He wrote: 'These different states which, taken as a whole, include all the symptoms of hypnotism, may be referred to three fundamental types: first, the cataleptic state; second, the lethargic state; and third, the state of artificial somnambulism. Each of these states, including, moreover, a certain number of secondary forms, and leaving room for mixed states, may be displayed suddenly, originally, and separately. They may also, in the course of a single observation, and in one subject, be produced in succession, in varying order, at the will of the observer, by the employment of certain methods. In this latter case the different states mentioned above may be said to represent the phases or periods of a single process.' The hypnotic state, in one or other of its stages, seems to be akin to that met with in some sleeping persons, as well as to the states known as trance, somnambulism, and catalepsy. Its physiological cause was presumed by Heidenhain to be some inhibitory arrest of activity of the ganglion-cells of the cerebral cortex, or, as the writer would rather put it, of certain tracts of these ganglion-cells, varying in their nature or situation in accordance with the different stages of the hypnotic condition that may exist.

The scientific study of the phenomena presented by hypnotised persons is unquestionably of great interest and importance from the point of view of the higher cerebral physiology. But whether the systematic induction of such a state can ever be used as a legitimate or potent means for curing disease, or even for the alleviation of certain distressing symptoms, must be left for the future to decide. The investigations that have been made in recent years are far from being decisive in favour of the method as a remedial agent, especially when taken in conjunction with the actual harm which may result from its induction in some nervous and impressionable persons. The good use to which it was put by Esdaile in India, as a means of inducing insensibility during surgical operations before the general introduction of chloroform, ought, however, never to be forgotten.

H. CHARLTON BASTIAN.

METALLIC.—A peculiar quality of sound, which the name suggests, either elicited by percussion or heard on auscultation, especially in connection with certain adventitious sounds in pulmonary cavities. See PHYSICAL EXAMINATION.

METAMORPHOSIS (μετά, a preposition signifying change : and μορφή, I form).—In a pathological sense this word signifies a form of degeneration, in which one tissue or substance becomes chemically changed into another, as, for example, albuminous structures into fat. See DEGENERATION.

METASTASIS } (μεβίστημι, I change place).
METASTATIC }

These terms are supposed to imply the translation of a disease from one part of the body to another, such as seems to occur occasionally in gout, rheumatism, mumps, and certain affections of the skin and mucous membranes. In modern pathology the term 'metastatic deposits' is sometimes applied to secondary new-growths.

METEORISM (μετεωρίζω, I raise up).—A synonym for tympanites. See TYMPANITES.

METRALGIA (μήτρα, the womb ; and ἄλγος, pain).—Pain in the womb. See UTERUS, Diseases of.

METRITIS (μήτρα, the womb).—Inflammation of the womb. See UTERUS, Diseases of.

MIASM (μαίνω, I pollute).—This term is used vaguely to include all poisonous emanations from the soil.

MICRO-ORGANISMS.—See BACTERIA ; ENTOMOZOA ; and the various diseases with which they are associated.

MICROSPORON (μικρός, small ; and σπόρος, a seed).—*Microsporon furfur* is the fungus of Tinea versicolor, and *Microsporon minutissimum* of erythrasma. See ERYTHRASMA ; and TINEÆ.

MICTURITION, Disorders of.—Under this term will be considered those conditions which interfere with the normal performance of micturition, regarded as a physical act. The following will be treated of as disorders of micturition :

1. *Undue frequency of micturition.*
2. *Diminished size and force of stream.*
3. *Retention of urine, partial and complete.*
4. *Urine passed by an abnormal channel.*
5. *Incontinence and overflow of urine in the adult.*

6. *Incontinence of urine in the child.*

1. *Undue frequency of micturition.*—This condition was formerly known as 'irritability of the bladder.' In all maladies of the bladder, in most that affect the kidney, and in some diseases of the rectum, unnaturally frequent micturition is present. It may vary in degree, and exist alone as a single symptom ; or it may, as is much more usually the case, be accompanied by other symptoms, which aid the diagnosis. Thus it is present in all the inflammatory conditions of the bladder after the administration of certain drugs, whenever calculi, foreign bodies, or tumours exist there, and in parasitic affections of the urinary organs. Also when the bladder is full, and either habitually does not empty itself, or when absolute retention is present, in

either case the want to pass water is frequent and pressing. It is often present in stricture of the urethra, and in inflammations of that passage ; also in chronic pyelitis, in chronic nephritis, in Bright's disease, in tubercular disease of the kidney, in diabetes mellitus, as a result of the increased quantity of urine, or when urine is morbidly acid, or alkaline. It is present likewise during hysterical states, and under emotional excitements in many persons of either sex, and whenever the watery elements of the urine are rapidly and abundantly secreted, arising either from dietetic idiosyncrasy, the administration of diuretics, or changes of climatic condition. The term *urgency* indicates the inability to postpone the act of micturition when the desire has occurred. It is associated with frequency, and is more particularly noticeable in disease affecting the bladder and urethra. *Straining* is another not uncommon symptom which accompanies vesical irritability. It is the uncontrollable and ineffectual endeavour to micturate which calls into play not only the ordinary muscular mechanism of micturition to its full extent, but also many other muscles of the body. It occurs, even when the bladder is free from urine, in inflammatory conditions of the organ and in stone. Straining then usually follows immediately after the act of passing water, and subsides almost directly. But the most pronounced form is seen in cases of retention. The attack or spasm commences with slight desire to micturate, rapidly increasing in severity and intensity until at last almost all the muscles of the body are brought into use in a fruitless endeavour to expel the contents of the bladder. Pain along the urethra, in the lower part of the abdomen, and in the back is often complained of. The struggle may continue for a considerable time, but it gradually decreases in severity and finally subsides altogether, leaving the patient tired and exhausted. Such spasms may come on at frequent intervals, depending to some extent on the degree of distension of the bladder. In acute cases of retention they may occur every quarter of an hour or so, but in chronic they are often absent for a considerable period, and are then only evoked by movement or other stimuli which so frequently produce the desire in health.

2. *Diminished size and force of stream.*—These may occur either with or without organic obstruction of the urethra. The size is always diminished in congenital narrowing of the prepuce or of the external meatus, though the force may be increased ; in organic stricture, in urethral calculus and growth, both are generally diminished, and mostly also in enlarged prostate, though loss of force is most marked. They may occur from inflammation of the urethra and prostate ; and when the power of the bladder to expel its contents is impaired by paralysis, atony, or by other causes, the force is greatly reduced but the size may remain comparatively full. Occasionally the channel is narrowed by irregular actions of the surrounding muscles, and thus 'spasmodic stricture' (an objectionable term) is spoken of as producing a diminution of the stream.

3. *Retention of urine.*—Retention of urine, partial or complete, is not to be confounded with 'suppression,' the latter being of course defective action of the secreting organ, so that no urine is produced, and the bladder remains empty. Retention is the result in almost all cases of mechanical obstruction, such as enlarged prostate from hypertrophy, tumour,

presence of blood-clots in the urethra or bladder, and occasionally from rupture of that organ. One of its most common causes is a narrow stricture of the urethra, especially when inflammation follows the use of instruments, or when associated with alcoholic excess; inflammation alone may also occasion retention, as during an attack of gonorrhoea. Impacted calculus is not infrequently the cause; sometimes also, but most rarely, the spasmodic action referred to above.

TREATMENT.—As the cause is a purely mechanical one in the great majority of instances, the remedy which should be applied without delay is also a mechanical one, namely, a catheter of appropriate size and kind. If a suitable instrument, however, is not within reach, medicinal agents may be of service until it can be obtained. At the head of these no doubt is opium, which allays involuntary straining, and sometimes thus enables the patient to relieve himself by the natural method, at all events to some extent. It should be given in full doses, for the purpose either of relieving the patient's suffering and anxiety, or of acting favourably on the function; and the error in practice which has been most common is to give doses of 10 to 15 minims of laudanum, when 30 to 40 or more were necessary, and might have been highly useful. Of course the form of opiate may be varied, according to the habits of the patient or the views of the attendant. Simple opium is merely mentioned here as the type. Rest in the recumbent position with buttocks and legs raised is to be enjoined. Local bathing, as hot as it can be borne, is also a valuable adjunct; as, for example, a hip-bath, commencing at 100° F., which may with advantage be carried gradually up to 110° in these circumstances. Diuretics, often given, are for the most part injurious; that is to say, when the cause is a mechanical one. As a general principle, also, it is not to be forgotten that active purgation commonly promotes the expulsive action of the bladder.

4. *Urine passing by abnormal passages.*—The urine may escape by abnormal channels, passing from different parts of the urethra to the surface, most commonly by that of the perinæum, constituting urinary fistula. This condition is necessarily named as one of the 'disorders of micturition,' but its treatment belongs exclusively to the surgeon.

5. *Incontinence and overflow of urine in the adult.*—It not infrequently happens that a man between fifty and sixty years of age finds himself gradually compelled to pass urine oftener than has been his custom hitherto, and that, the tendency still increasing, he is compelled to pass it every hour or two, both by day and night; and sometimes even, especially if not relieved by treatment, he may pass it during sleep. During the earlier stages of the affection, it is by no means uncommon that the individual learns or believes that his experience is natural to age, and is either not amenable to treatment, or is not worthy of serious notice. Again, the condition described is often loosely spoken of as 'incontinence' of urine; of which, however, it is not only not an example, but indeed indicates the presence of a condition precisely contrary. The cause of these symptoms is a bladder unable to empty itself, always therefore partially if not completely filled, from which the surplus must be either frequently discharged, or be passed 'incontinently.' The important point, then, is never to lose sight of the fact that frequent micturition, and above all

urine involuntarily passed by elderly men, in nineteen cases out of twenty indicates retention (requiring the catheter), and not incontinence.

True incontinence, which means inability to retain, on the part of the bladder, is a very rare occurrence, and is present only in cases of disease in the nervous system producing paralysis in other parts of the body, as well as the bladder. When the bladder-symptoms alone are present, and no signs of paralysis elsewhere exist, it may be held as almost absolutely certain that the bladder itself is not paralysed. It may be over-distended with fluid from enlarged prostate; or its coats may be thinned and atonic, and so unable to contract on their contents.

TREATMENT.—In these partial retentions of urine, producing its overflow and involuntary discharge, the remedy consists in the more or less frequent use, according to circumstances, of a soft or flexible catheter, under rigid aseptic precautions, and the case is mainly surgical. There are some instances in which restoration of the power of the bladder may be attempted by medicinal agents, such as strychnine and iron, or by electricity, but their effect is little or none, apart from the habitual emptying of the organ by artificial means. In some cases perhaps they may be advantageously associated with the surgical treatment.

6. *Juvenile incontinence.*—In the earliest periods of childhood an undue frequency of passing water is often to be observed among individuals of both sexes, more commonly in boys than in girls. As age advances the infirmity usually lessens, and then disappears; while in exceptional instances it continues, without change, to puberty, and even for some years after that period has arrived. But the peculiarity of the case is that the urine is passed unconsciously during sleep, and this forms the most serious symptom. In spite of all precautions, a quantity of urine is discharged every night during deep sleep, an occurrence of which the child is quite unaware, and which as he advances in age he is wholly unable to control, however strong may be his disposition to do so. On the bladder becoming distended reflex action of the vesical muscular coats takes place, and the contents are discharged. The flow of urine is determined, as it would appear, not by inability on the part of the bladder to retain the ordinary quantity of urine, for the patient does so by day, but by its undue excitability or readiness to contract, so that the water is passed while consciousness is lost, during sleep. In a few instances, certain aberrations from a good standard of health seem to favour the production of these phenomena, especially sources of irritation in the rectum, which produce activity in that muscular apparatus, involving also the kindred muscles of the bladder, which are so closely associated. Thus the presence of ascarides, thread-worms, rectal polypi, fissured anus, or urethral caruncle, may suffice to occasion expulsive action in the bladder. During the period of infancy and early childhood the nervous system is highly impressionable, and the habit in question being accidentally set up, its persistence may result solely from repetition through the force of custom, long after the original cause has disappeared.

Sometimes slight malformations of the male organ favour the occurrence of incontinence; such as a narrow meatus, or a long prepuce which is never retracted and is consequently in an unhealthy state.

Precocious development and extreme activity of the mental faculties, producing disturbed sleep,

seem to favour the occurrence of incontinence. On the other hand, it is sometimes associated with a morbid deficiency of intelligence. In many of the cases an hereditary tendency can be traced.

TREATMENT.—The treatment ordinarily necessary may be to some extent inferred, when examination of the patient has determined the presence or absence of the conditions named. This done, the next indication is to subdue the activity of the expulsive function of the bladder by some agent which possesses that power. The most powerful for this purpose is undoubtedly belladonna. Thus, if administered to an adult whose powers of expelling urine are feeble, such, for example, as are commonly met with in advancing years, complete retention of urine is often produced. Now, as has already been observed, in not a few of the cases of so-called 'juvenile incontinence,' its existence is due solely to persisting habit after the original occasion of it has long ceased; and these are almost certainly and sometimes rapidly cured by administering the drug in question. The object is to induce a partial paralysis of the bladder for a period of some weeks, and, if the case is obstinate, even for two, three, or four months, and by this means not only to destroy the old habit, but to develop a new one, namely, a habit of retention, and the annoyance disappears entirely and for ever. On meeting, therefore, with a case, whether in childhood or youth, the first indication is to correct any manifest deviation from the ordinary standard of general health; and, secondly, to administer belladonna persistently. Small doses, suited to the age of the patient, suffice at first, and may be given every afternoon and evening only—say from three to six minims of the tincture on each occasion during the first week. In the second and third weeks of treatment, the dose may be augmented one-fourth; in the fourth and fifth weeks the original dose is raised a third or half; in the meantime some improvement will almost certainly be manifest. Since the ability to bear belladonna increases rapidly as the system becomes habituated to it, a larger dose may be given during a further term of three successive weeks, by which time the involuntary discharge of urine probably ceases. If not, a gradually increased dose must still be continued. After this the dose may be gradually diminished, and at a rate more rapid than that by which it was augmented. The habit of retention has probably been formed by this time, and when cessation from medicine takes place, no recurrence of the symptoms will be observed. But it must be confessed that a troublesome minority is met with in which the influence of the belladonna has not been permanent. It almost invariably produces some improvement, however, and it is worth while to be careful that the drug has been well prepared. There still remain modes of treatment of a local character, which may prove successful in these cases. These do not include blisters on the sacrum; apparatus to prevent the patient lying on his back, when asleep; arrangements to arouse him during the night once or twice to pass water voluntarily, and such measures—all of which are palliative means, and do little towards a radical cure. The use of a flexible bougie, small of course for children, passed daily, and removed in the course of a minute or so, is sometimes successful, especially when both nocturnal and diurnal incontinence are associated. But if this fails, the injection of a solution of nitrate of silver by means of a sufficiently long tube into

the prostatic portion of the urethra and neck of the bladder has been found in the hands of some surgeons a valuable remedy. The process generally known to surgeons as 'instillation,' by means of a syringe and a flexible tube, is perhaps the best. For young women up to the age of eighteen or twenty in whom this unfortunate infirmity still exists, it is said to be almost always successful. It should be applied immediately after the bladder is emptied, in quantity, say, of a drachm, and of a minimum strength of ten grains to the ounce, up to treble that strength if necessary for subsequent applications. Enough should be employed to produce decided smarting, which shall continue for a day or two. A week or two should be permitted to elapse between each application.

It would not be right to omit the mention of other remedies besides belladonna, which may be used either alone or in combination with it. Such are the tincture of the perchloride of iron, strychnine, and bromide of potassium. The last-mentioned, given at night only, has sometimes a manifestly beneficial effect.

H. T. HERRING.

MIDDLE PARK HOT SPRINGS, in Grand County, Colorado, U.S.A.—Thermal Waters. See MINERAL WATERS.

MIGRAINE.—A synonym for megrim. See MEGRIM.

MILIARIA (*milium*, a millet-seed).—SYNON.: Sudamina; Miliaria crystallina; Fr. *Miliaire*; Ger. *Friesel*.

DEFINITION.—A superficial non-inflammatory vesicular eruption of the skin, generally associated with profuse sweating.

DESCRIPTION.—The proximate causes of miliaria are heat and sweating, and are therefore especially seen in acute rheumatism, acute pneumonia, and typhoid fever. The millet-sized vesicles—either few or very many—are developed between the layers of the stratum corneum, owing to the free flow of the secretion, together with occlusion of the orifice of the ducts; are generally discrete; and are dispersed irregularly over the chest, neck and abdomen, and elsewhere. They are thin-walled, and contain at first pellucid sweat of faintly acid reaction; when the serum becomes milky and opaque, the eruption is called *miliaria alba*. When the retention is followed by inflammation the term *miliaria rubra* is applied to the general redness of the skin of the affected areas, which are crowded with discrete vesicles on inflamed bases. When left to themselves the vesicles subside and dry up into an extremely thin scale. Miliaria, therefore, calls for no special treatment. See SUDORIPAROUS GLANDS, Diseases of.

JOHN HAROLD.

MILIARY ANEURYSMS.—Minute dilatations in connection with the small blood-vessels; especially met with in the brain. See BRAIN, VESSELS OF, Diseases of.

MILIMUM (*milium*, a millet-seed).—SYNON.: *Grutum*; *Strophulus albidus* (Willan).

The name *milium* is applied to small, firm, globular, pearly-white bodies, few or numerous, seen under the cuticle especially of the eyelids, cheeks, temples, orbits, and occasionally on the male and female genitals. In size they vary almost

as much as ordinary pins' heads. They are not accompanied by any sign of inflammation, are usually arranged asymmetrically, and may undergo calcification ('*cutaneous calculi*'). They are unattended by subjective sensations. Infants and young adults are most frequently affected.

Milia consist of the 'distended acini' of sebaceous glands, the ducts of which have been occluded. According to Robinson, of New York, milia originate from 'miscarried embryonic epithelium from a hair follicle or from the rete.'

TREATMENT.—Milia may be opened by a fine needle, and the contents evacuated by curetting; or recourse had to electrolysis.

See PEMPHIGUS; COLLOID MILIUM.

JOHN HAROLD.

MILK, Poisoning by.—See FOOD, POISONOUS.

MILK-FEVER.—SYNON.: Ephemeral Fever; Fr. *Fièvre de Lait*; Ger. *Milchfieber*.

A term applied to a transient rise of temperature which sometimes occurs on the third or fourth day after delivery, on the supposition that it was due to the onset of lactation. It is now generally attributed to constipation, emotion, or septic absorption, though some believe it may occasionally be due to unusual tension in the breasts. Any rise of temperature on or about the third day should be carefully investigated, as it rarely occurs if antiseptics have been carefully used during labour. See PUERPERAL DISEASES.

MILLAR'S ASTHMA.—See THYMUS GLAND, Diseases of.

MIMESIS (μιμῆσαι, I imitate).—A term applied to the phenomena of a disease, which resemble or imitate those of another disease.

MIND, Disorders of.—See IDIOCY; and INSANITY.

MINERAL WATERS.—DEFINITION.—Mineral Water is the name given to those waters which, on account of the different saline or gaseous substances which they hold in solution, or of their elevated temperature, are used in the treatment of disease, either internally or in the various forms of baths.

The science that treats of the effects of mineral waters and baths on a great number of chronic maladies is called *Balneotherapeutics*. In a wider sense this branch of medicine comprises also the use of sea-baths and of common water, but these subjects are treated in separate articles. See HYDROTHERAPEUTICS; and SEA-AIR.

Courses of mineral waters and baths are to be regarded as methods of treatment analogous to courses of other remedies; but they are much more complicated, not only because many of the mineral waters are in themselves compound remedies containing several active substances in combination, but also because in most courses of waters or baths the invalid is influenced in body and mind by several other powerful agents: such as travelling, change of social conditions, occupation, scene, diet, and habits in general, mostly including increased exercise; and by change of climate. Each of these influences has in itself a powerful action, and to their combination we must often ascribe a great part of the curative effects of balneotherapeutic courses; they ought therefore to be carefully considered in

every individual case as part of the plan prescribed.

GENERAL COMPOSITION AND CLASSIFICATION. The principal constituents of mineral waters are: Water, sodium, magnesium, calcium, and iron; combined with hydrochloric, sulphuric, carbonic, and hydrosulphuric acids, the two latter existing also in some waters 'free,' that is, uncombined with bases. Nitrogen and oxygen are likewise present in most mineral waters in various proportions; and in some there are also silica, arsenic, bromine, iodine, lithium, manganese, potassium, alum, and other substances in small quantities.

The substances dissolved in mineral waters are derived from the surface-soil and the rocky strata through which the water deposited from the atmosphere passes. The dissolving power of this water is much increased by the gases which it absorbs, especially carbonic acid and oxygen. The constitution of mineral waters, therefore, varies according to the nature of the strata through which they have passed.

The different mineral waters may be grouped in various ways, as, for instance, according to their chemical constituents, their temperature, their geological origin or geographical distribution, or their physiological or therapeutical actions.

The chemical classification, imperfect though it is, offers the advantage that it directs the attention at once to the most important constituents of the water. Some of the classes, however, are not named according to the substances contained in them in the *largest quantity*, but according to those considered most *potent*; such as the iron, arsenic, and sulphur waters. Another difficulty in the classification is, that some mineral waters contain several active substances in sufficiently large proportions to allow of their being placed in different classes; and, again, that some springs are so deficient in active principles as to render it doubtful where to place them. Of these latter, some appear to owe their virtues to the water alone, and its temperature, aided by the climate with which they are associated. Beginning with the latter as the most simple, we may group the mineral waters in the following principal classes:

I. *Simple Thermal Waters*; II. *Common Salt or Muriated Saline Waters*; III. *Alkaline Waters*; IV. *Sulphated Saline Waters*; V. *Iron or Chalybeate Waters*; VI. *Arsenical Waters*; VII. *Sulphur Waters*; VIII. *Earthy and Calcareous Waters*.

Some of the waters are chiefly used for bathing, others more for drinking, the majority for both purposes. In the consideration of the uses of the different spas, it is important to distinguish between the effects produced by the baths and those caused by the internal use of the waters.

The term 'baths' comprises not only the ordinary tub-bath, but also swimming-baths, or piscines; partial baths for the feet, the hands, and other parts; douches of great variety; vapour-baths; carbonic-acid-baths; and mud-baths. At many places also inhalations of vapour and pulverised spray form part of the treatment.

I. *Simple Thermal Waters*.—The simple thermal waters are characterised by poverty in solid and gaseous substances, and therefore by low specific gravity; by perfect transparency; by great softness; and by elevated temperature—varying in the different spas from about 80° to over 150° F.

Some of them contain nitrogen in larger proportions than the gases of waters usually do, others more oxygen. They are often called *indifferent* waters, on account of the absence of special mineralisation; and also *wild baths* (*Wildbäder*), on account of their being usually situated in wild mountainous regions.

ACTION.—The water of this class of spas when taken internally probably acts only as ordinary, pure, warm water. By the drinking of warm as well as of cold water, the stomach is washed out; the secretion of bile, saliva, pancreatic juice, urine, &c., is increased; the tissue-change is augmented, and the removal of effete matters from the tissues and blood promoted; and by the acceleration of the retrogressive tissue-change, the progressive tissue-change becomes facilitated. As differences between warm water and cold water for drinking purposes, we may mention that the latter acts more as a local excitant on the stomach, while the former is more easily absorbed, and makes less demands on the powers of the constitution, by not causing any expenditure of heat.

The simple thermal waters are much more used for *bathing* than for drinking-courses; and the baths, as such, have probably the effects of ordinary warm baths, varying according to the temperature of the baths, and the time spent in them.

As the *fundamental effects of warm baths*, which effects form part of the action of all kinds of warm baths, simple as well as mineralised, we may regard—

(1) That they soften and cleanse the skin more rapidly than cold baths, and prepare it for perspiration.

(2) That they equalise and diminish the loss of heat, and, according to the temperature of the bath, lessen or prevent it altogether; and that, in the hot bath, heat is even added to the body.

(3) That the flow of blood to the surface and its circulation in the skin are promoted.

(4) That the organic functions and the tissue-change are slightly stimulated, or rather facilitated, without any strong reaction on the part of the organism.

(5) That the nervous system and muscular irritability are calmed.

(6) That the absorption of exudations is promoted.

These effects, as already mentioned, vary considerably with the degree of heat. In the *tepid bath* (from 80° to 95° F.) the central nervous system and the action of the heart are but slightly influenced; in the *warm bath* (from 96° to 102° or 103° F.) the heart's action is quickened, but the respiration is generally only slightly affected; in the *hot bath* (from 103° to 110° F.) the central nervous system becomes much more excited; not only is the heart's action further accelerated, but the respiration becomes rapid, and sometimes irregular; and the hyperæmia of the skin leads to perspiration on removal from the bath. Baths of a temperature above 110° F. are scarcely ever used, and only for a very few minutes.

The effects vary also considerably, according to the duration of the immersion.

USES.—The *drinking-courses* of these waters may assist in the treatment of irritable forms of affections of the throat, stomach, and intestines, often associated with spasmodic cough, cardialgia, constipation from sluggish secretion of bile and intestinal secretions; they do so by diluting these

secretions, by increasing the tissue-change, and by removing used-up material; in this way they are useful in chronic rheumatism and gout.

One of the main uses of the *simple thermal baths* is to allay over-excitability and hyper-sensibility of the nervous system in its various spheres; thus they often act beneficially in cases of neuralgia, hyperæsthesia, painful menstruation, and hysterical tendency. Their reputation in painful wounds and cicatrices is historical. In these cases, as well as in chronic rheumatism in its various forms and sciatica, the hotter are more useful than the tepid baths. In some forms of paralysis and loss of muscular power depending on peripheral changes, such as exudations into nerve-sheaths, good effects are produced; but if they are caused by changes in the centres of the nervous system, not much is to be expected. In gout the internal use of other mineral waters is generally required, but as second courses the simple thermal waters are often useful; in many delicate gouty persons, however, the balneotherapeutic treatment ought to be restricted to courses of tepid baths, aided by climate and diet. Most of these conditions can be also treated with other waters.

The ordinary thermal bath requires in many cases the assistance of douches and massage; and if atheroma of the cerebral vessels be suspected, douches are preferable to the ordinary hot baths, either alone or in combination with massage.

ENUMERATION AND SELECTION.—The choice of a simple thermal spa is to be guided, not by the name of the disease alone, but also by the state of constitution, and many concomitant circumstances. The simple thermal waters deserve, *cæteris paribus*, the preference, when gentle management is required—when it is desirable to make as slight demands as possible on the powers of the constitution. Their action is in this respect greatly assisted by the mountainous climate or large forests in which they

Name	Country	Elevation (approximate). Feet	Temperature of springs. Fahrenheit

Teplitz	Bohemia	650	95°-120°
Lucca	Italy	500	100°-120°
Dax	France	130	127°-140°
Bath	England	100	100°-120°

are often situated. The selection of a special spa in a given case depends on the nature of the case in the widest sense ; on the degree of elevation which is desirable ; on the means of treatment obtainable and customary at the different spas, including the most important agent—the resident physician ; on the accommodation, the food, manner of living, and social conditions ; on the distance and means of reaching the spa ; on the travelling power of the patient ; and on many other circumstances. Information on these subjects can only be obtained by the study of larger works, and by personal visits. We give above only the names of the principal spas of this class arranged according to their elevation.

Many other slightly mineralised warm waters, whose principal action is to be referred to water and heat, might be mentioned here, while several of the places contained in the list, as Leukerbad, Bormio, Bagnères de Bigorre, and Bath, might find places in other divisions.

The very hot Algerian baths, Hammam-Meskoutin, Biskra, and Hammam-R'irha, the last beautifully situated some sixty miles from Algiers, belong likewise to this class.

The United States of America are rich in simple hot springs, which are partly already in use, partly awaiting development. Sooner or later they will equal and perhaps surpass the most celebrated thermal waters of Europe. We will only mention here a few of them : the ' Hot Springs ' in Virginia ; the ' Hot Springs ' in Arkansas ; the ' Calistoga Hot Springs,' California ; the ' Geysers,' California ; the ' Paso Robles Hot Springs ' in California ; the ' Idaho Hot Springs ' in Colorado ; the ' Warm Springs ' in North Carolina ; the ' Warm Springs ' in Georgia ; ' Lebanon Springs ' in Columbia county, New York ; the ' Warm Springs ' and the ' Healing Springs ' in Bath county, Virginia.

Allied in their action, though more powerful in their demands on the system and in their effects, are the natural hot-vapour baths in the large cave of Monsummano in Upper Italy, and in the smaller excavation in the rocks of Battaglia in the Euganean mountains.

II. Common-Salt or Muriated Saline Waters.—COMPOSITION.—Common salt, or chloride of sodium, is the principal solid constituent of the waters of this class, but this substance is contained also in many other mineral waters, especially in some alkaline, some sulphur, and some sodium-sulphate waters, and has a considerable share in the effects of these waters. Some of the springs in this class contain also appreciable quantities of chlorides of calcium and magnesium, of iron, and of carbonates of sodium, lithium, magnesium, and lime, by which their action is modified.

ACTION.—In order to appreciate the action of the common-salt waters, we must bear in mind that common salt forms part of all the tissues and juices of the body ; that it promotes digestion ; that it is essential to the formation as well as the disintegration of cells and tissues ; that it stimulates not only the retrogressive, but also the progressive tissue-change or nutrition of the body ; and that it is a great agent in the processes of secretion and absorption. Chloride of sodium stimulates the secreting apparatus of the stomach and intestines, and hence the action of the bowels and the circulation of the portal system, and indirectly the general circulation. It quickens the tissue-change ; and

through this, as well as the increased circulation, it promotes absorption of pathological products, without lowering the organism. In larger doses, however, beyond about five drachms *per diem*, irritation of the mucous membrane of the stomach and intestines may be produced. The action of the common-salt waters is modified by their accompanying properties, especially by the carbonic acid contained in them, by their temperature, and by the degree of their concentration.

The *carbonic acid* in this and other classes of waters quiets the sensitive nerves of the stomach ; stimulates the secretion and peristaltic action of the stomach and bowels. In large quantities, however, if not rapidly ejected by eructation, it may, by distending the stomach, interfere with the action of the heart, or may produce, on being absorbed, poisonous effects on the blood and nervous system. The presence of carbonic acid in salt waters increases the effects of chloride of sodium on the stomach and intestines, and by accelerating the passage of the waters from the stomach into the intestinal canal, promotes the action of the bowels.

Elevation of the temperature of the water produces more rapid absorption, and thus diminishes the local and increases the more distant and constitutional effects.

Concentration increases the local stimulation.

As to the action of these waters in the form of *baths*, the chloride of sodium and other chlorides (though any absorption through the skin of these and other salts contained in mineral waters is doubtful, or, at all events, forms only a small part of their therapeutic effects) stimulate the cutaneous ends of the nerves and the capillaries, and promote through this the nutrition and tone of the skin, and indirectly the tissue-change, an action which is heightened by the presence of carbonic acid, as witnessed at the gaseous saline baths of Rehme and Nauheim. The action of the salt and of the carbonic acid on the skin is, however, not to be regarded as merely local, but as transmissible from the nerve-ends to the various nerve-centres, and producing through these reflex effects, especially on the heart and blood-vessels, but also on other organs.

USES.—Salt waters and salt baths are useful in weakness of the skin ; in tendency to rheumatic fever or bronchitis ; in retarded convalescence from acute and chronic illness ; in enlargements of joints from preceding inflammation ; in many forms of anæmia and chlorosis—especially those where iron alone is not borne ; in numerous cases of tropical cachexia ; and in cases of sluggish circulation in the portal system, which leads to innumerable varieties of digestive troubles, to congestion of the liver, and of the pelvic organs in women, and to piles.

ENUMERATION AND SELECTION.—The same classes of cases, as far as the name goes, are treated alike by muriated alkaline and sulphated waters. The individual conditions must guide the practitioner in deciding for either the one or the other kind of waters, and for the special spa, according to the strength of the springs, the additional ingredients, such as lithium and arsenic at Baden-Baden, the amount of carbonic acid, and the climatic and concomitant conditions. Spare and pale persons, we may mention, mostly bear the common-salt waters better than strongly alkaline and sulphated waters. Common-salt waters are to be found in almost all countries ; we only give the most important or best known. In *England*: Droitwich—

perhaps the strongest of all brines, with good arrangements, Nantwich, Ashby-de-la-Zouche (Ivanhoe Baths), Middlewich, Woodhall, Harrogate, and Llandrindod; Leamington and Cheltenham contain likewise much common salt, in addition to sulphate of sodium. In *North America*: St. Catharine's Wells, Michigan Congress Spring, Spring Lake Well, Fruit Port Well, the celebrated Saratoga Springs, and the Ballston Spa. In *Germany*: Kissingen, Homburg, Rehme-Oeynhausien, Nauheim, Kreuznach, Soden, Pyrmont (which contains salt as well as iron springs), Wiesbaden, Hall in Austria, Hall in the Tyrol, Hall in Württemberg, Reichenhall, Ischl, Kreuth, Dürkheim, Kosen, Koenigsdorff-Jastrzemb, Krankenheil, Mondorf, Salzungen, Canstatt, Cronthal, Baden-Baden, Niederbronn (Alsatia), and several others. In *France*: Bourbonne-les-Bains, Lamotte-les-Bains, Bourbon-l'Archambault, Bourbon-Lancy, Balaruc, Salins, and others. In *Italy*: Ischia, Castellamare, Castro-Caro, Monte Cattini, Salsomaggiore, La Porretta. In *Switzerland*: Bex and Rheinfelden. In *Spain*: Las Caldas de Besaya, Las Caldas de Estrae, and Las Caldas de Montbuy.

III. Alkaline Waters.—COMPOSITION.—The alkaline waters contain *carbonate of sodium* as a prominent constituent; they are also more or less rich in *carbonic acid*; and some are distinguished by so large a proportion of *chloride of sodium* as to warrant a subdivision into—(1) *simple alkaline waters*; and (2) *muriated alkaline waters*.

ACTION.—Oxidation and tissue-change seem to be greatly influenced by the presence of soda; various proteid bodies seem to be kept in solution by it; it has a considerable share in the secretion of saliva and bile, and in the digestive processes; and, according to Liebig, it acts as a vehicle for the carbonic acid from the blood to the lungs.

Carbonate of sodium may be considered as an antacid, as a diuretic, as a promoter of tissue-change, and as a solvent. The beneficial effects of alkalis are in general produced only by a systematic use of *small doses*; while *large quantities* cause emaciation by their excessive solvent effect, and diminish the tissue-change by their depressing influence on the heart's action. The action of soda differs in this respect from that of chloride of sodium, which even in considerable doses increases the tissue-change, and does not so easily exercise an emaciating effect.

USES.—The conditions in which alkaline waters are mostly employed are certain forms of dyspepsia, with undue acidity of the stomach; congestive conditions of the liver from sluggish portal circulation; tendency to gall-stones; diabetes; uric-acid diathesis, and its results—gravel and lithiasis; some forms of gout; and especially chronic catarrhal affections of the mucous membranes of the respiratory, digestive, and genital organs.

ENUMERATION AND SELECTION.—Where it is necessary to improve the state of the blood, or to avoid emaciation, the muriated alkaline are preferable to the simple alkaline waters.

1. The principal spas with *simple alkaline waters* are—(a) *Hot*: Vichy, Neuenahr, Mont Dore, Chaudes Aigues, and Neris, the last three being feebly mineralised; (b) *Cold*: Vals, Salzbrunn, Le Boulou, Evian, Bilin, Apollinaris, Gerolstein, Fachingen, Geilnau, Wilhelmsquelle, Taunus, Giesshübel, Soultzmat, and Marcols. In *North America*—the Bladon Springs in Alabama, the Sheldon Springs in Vermont.

2. The chief *muriated alkaline waters* are—(a) Ems, Royat, and La Bourboule, which represent the *hot springs*; (b) Luhatschowitz, Selters, Gleichenberg, Roisdorf, Rosbach, Vic-sur-Cère, and Toennistein, which are *cold*. In *North America* the Congress Springs in California, and the St. Louis Spring in Michigan, belong to this class. The so-called California Seltzer Springs are peculiar in so far as they contain a larger quantity of carbonate of magnesium (10 grains in a pint) than of either carbonate or chloride of sodium. These springs seem therefore to offer advantages in oxaluria, and in some gouty persons.

We ought to remark that several of the waters in this class, especially La Bourboule and Mont Dore, contain *arsenic* in appreciable quantities, and will, therefore, be mentioned again under arsenical waters, while others contain lithium, as Royat.

IV. Sulphated Waters.—COMPOSITION. We include under this term those springs which are characterised by a preponderating amount of the sulphates of sodium or magnesium, or both sulphates together. They may be subdivided into (1) *simple sulphated waters* or *bitter waters*; (2) *alkaline sulphated waters*, which latter contain also carbonate and chloride of sodium; and (3) *muriated sulphated waters*.

ACTION.—The *bitter salts* can scarcely be said to be constituents of the organism; they seem to act by stimulating, and in larger doses irritating, the mucous membrane of the stomach and alimentary canal, causing thin watery secretion, and in large doses diarrhoea. Sulphate of sodium is less irritating than sulphate of magnesium. The peristaltic action of the bowels is likewise increased by them. Their continued employment is apt to cause emaciation. By the presence of carbonate and chloride of sodium, the action of the bitter salts is modified.

USES.—The bitter waters are useful in habits of constipation with sluggish portal circulation, in hæmorrhoidal tendencies, in congestion and enlargement of the liver and spleen, in some forms of dyspepsia, in gall-stones and allied affections, in gouty conditions, lithiasis, and diabetes; and, *ceteris paribus*, have in stout and in so-called phlegoric persons the preference over the muriated saline waters.

ENUMERATION AND SELECTION.—Where prolonged courses are required, the weaker sulphated waters, and especially the alkaline sulphated waters, and the muriated-sulphated waters, are to be preferred; while the stronger bitter waters are more frequently selected for occasional purging doses. (1) The principal *simple sulphated* or *bitter waters* are: Pullna, Saidschutz, Sedlitz, Birmensdorf, Åsculap, Apenta, Ivanda, Hunyadi János and other springs near Ofen, Rubinat, Las Caldas de Cuntio, Aranjuez, Friedrichshall, and Mergentheim, the two latter being also rich in chlorides. (2) The principal *alkaline sulphated waters* are Carlsbad, Marienbad, Tarasp-Schuls, Franzensbad, Elster, and Bertrich. The constitution and the action of the waters of Carlsbad and Bertrich are modified by their thermal nature. *North America* possesses some milder springs of this class: Estrill Springs, Crab Orchard Springs, Bedford Springs, Midland Well. (3) The best known muriated-sulphated waters are Brides-les-Bains, Leamington, Cheltenham, and St. Gervais.

V. Iron or Chalybeate Waters.—COMPOSITION.—Iron is contained in the majority of mineral

waters; but we regard as iron waters only those where the quantity of iron is, in proportion to the other constituents, so far predominant as to give a special therapeutic character to the springs.

ACTION.—The formation of blood-corpuscles, the contractility of the blood-vessels, the oxidation and the production of heat, and the general nutrition of tissues seem to be favoured by the use of iron waters. A small quantity only of iron seems to be absorbed by the stomach; none through the skin. The action of chalybeate baths seems to be due to the influence of the water and carbonic acid only.

USES.—The conditions most benefited by chalybeate waters are the various forms of anæmia, or poverty of blood and particularly of red corpuscles, especially when caused by actual loss of blood, supuration, or previous acute or chronic disease. The liver and digestive organs, however, must be in healthy working order, while in cases of anæmia accompanied by congestion of the liver and spleen, chalybeates alone are rarely useful, but must be preceded or modified in their action by the use of saline waters or other aperients; and this is often the case not only in anæmia of Indian and malarial cachexia, but also in chlorosis. Neuralgia, sterility, impotency, and general debility are often benefited through improvement of the general health. Those iron-waters are most useful which contain the iron in the form of the bicarbonate of the protoxide, kept in solution by free carbonic acid.

ENUMERATION AND SELECTION.—Iron springs are (1) *comparatively pure*, that is, containing only a few grains of other substances in sixteen ounces of water: Schwalbach, Spa, Brückenaue, Schandau, Lieberda, Flinsberg, Freienwalde, Recoaro, Königswarth, Liebenstein, Altwasser, Tunbridge Wells, and one of the springs at Harrogate; (2) *compound iron-springs*, that is, which contain, in addition to iron and carbonic acid, a moderate quantity of other salts, especially the carbonates of sodium, calcium, and magnesium, the sulphates of sodium, magnesium, and calcium, and common salt: Aratapak, Orezza, Pyrmont, Driburg, Rippoldsau, Griesbach, Antogast, Petersthal, Elster, Bocklet, St. Moritz, Reinerz, Godesberg, Cudowa, Imnau, Bussang, Ceresole Reale, and Santa Catarina. In North America: Bailey Springs, Stafford Springs, Green-castle Springs, Estill Springs, Schooley's Mountain Springs, Montvale Springs, Rawley Springs. Somewhat different in their action and less easily assimilated are the springs containing *sulphate of iron*. Representatives of this class are, in America—the Oak Orchard Acid Springs, the Bath Alum Springs, Stribling Springs, Bedford Alum Springs, and Variety Springs. The best known in Europe are: Flitwick in Bedfordshire, Muskau in Silesia, Parad in Hungaria, Alexisbad, and Ratzes. Rich in sulphate of iron in combination with *arsenic* are the waters of Roncegno and of Levico in the Austrian Tyrol, which will be mentioned among arsenical waters; they are very powerful, and can only be taken in small doses.

VI. Arsenical Waters.—Arsenic occurs in sufficiently appreciable quantities in some mineral waters to produce an alternative action in cases of anæmia, and various cachectic conditions, especially malarial cachexia, and in some chronic skin-diseases. We have mentioned already in the preceding group (iron-waters) two of the strongest arsenical waters, viz.: Levico and Roncegno in the Austrian Tyrol. Weaker springs of arsenic in combination with iron

are: Ceresole Reale in Upper Italy, Val Sinestra near Tarasp; Vic-sur-Cère, Sylvanès and Bussang in France; Cudowa and Linda-Pausa in Germany; Grèbernük (Grebernicza) in Bosnia. Combined with alkaline and muriated ingredients we have already mentioned La Bourboule and Mont Dore in France, and we may add Court-Saint-Etienne in Belgium. Arsenic is also contained in some springs of Royat, Saint-Nectaire, Saint-Honoré, Vichy, Vals, Uriage, Lamalou, Bath, Baden-Baden, Plombières, Porretta, &c.

VII. Sulphur-Waters.—**COMPOSITION.**—Among sulphur-waters we class those springs which contain either sulphuret of hydrogen, or the sulphuret of sodium, calcium, potassium, or magnesium in an appreciable and constant proportion. They are partly thermal, partly cold; and some of them, especially Aix-la-Chapelle, Uriage, the Columbia Springs in New York, and the Louisville Artesian Well in Kentucky, U.S.A., contain a considerable proportion of common salt and other solids, which are to be taken into consideration in the appreciation of their effects.

ACTION.—It is difficult to describe the physiological effects of the sulphur-waters, so far as they depend on such minute quantities of sulphur as are contained in them. Sulphur-water baths seem to act in the same manner as simple baths. If the waters are taken internally, some sulphuretted hydrogen is probably absorbed, entering the circulation through the portal vein. The pure sulphur-waters exercise a constipating rather than an aperient effect. The feces become mostly blackened from sulphuret of iron. The protracted use of these waters is apt to lead to a certain degree of anæmia, possibly from the action of the sulphur on the iron of the blood-corpuscles.

USES.—Sulphur-waters are mostly used in combined bathing and drinking courses, as also by inhalation; in cases of metallic poisoning; in congestion of the liver; piles; bronchial, laryngeal, and pharyngeal catarrh; in numerous cutaneous affections, especially the herpetic dyscrasia of the French; in rheumatism and gout; and in constitutional syphilis.

ENUMERATION AND SELECTION.—The best known *thermal sulphur-waters* are: Eaux Bonnes, Eaux Chaudes, Cauterets, Saint Sauveur, Barèges, Bagnères de Luchon, Ax, Escaldes, Le Vernet, Amélie-les-Bains, Uriage, Allevard, Aix-les-Bains, Aix-la-Chapelle, Baden in Austria, Baden in Switzerland, Lavey, and Schinznach in Switzerland; Acqui in Northern Italy; Battaglia and Abano in the Euganean mountains; Panticosa in Spain; Mehadia, and other springs in Hungary; and Helouan or Helwan, near Cairo. *Cold sulphur-springs* are: Eilsen, Nenndorf, Langenbrücken, Weilbach, Meinberg, Reutlingen, Enghien, Challes, Stachelberg, Heustrich, Gurnigel, some Harrogate springs, Llandrindod and Builth in Wales, Moffat and Strathpeffer in Scotland, and Lisdoonvarna in Ireland. There are also several important sulphur-springs in the United States of America.

VIII. Earthy and Calcareous Waters.—**COMPOSITION.**—As *earthy and calcareous waters* we designate those springs in which the earthy substances, especially carbonate and sulphate of calcium and carbonate of magnesium, form the prominent constituents.

ACTION.—In the shape of baths, the earthy waters act almost in the same way as ordinary

water baths. Internally taken, the carbonate of calcium exercises an antacid and a soothing effect on the mucous membrane of the stomach and intestines, and together with the sulphate of calcium is slightly astringent and constipating. If lime is absorbed, it may assist in the formation of bone, and may exercise also a soothing effect on other mucous membranes.

USES.—These waters, according to their composition, are useful in digestive troubles with tendency to acidity, diarrhoea, and undue irritability of the mucous membrane. They are employed also in osteomalacia, rachitis, and tuberculosis; and, further, in some skin-diseases, especially in eczema, and psoriasis, where, however, the long continuation of the warm bath, that is, the soaking of the skin, is of more importance than the nature of the solid constituents contained in the water. Some of these waters possess a great reputation in chronic catarrh of the bladder, and in tendency to gravel and stone; but probably the large quantity of water consumed, as, for instance, at Contrexéville, and the consequent dilution of the urine and the washing out of renal tubules, are here to be regarded as the principal causes of the useful effect. Some of these waters, especially Contrexéville, are also often employed in uric-acid diathesis, and in the glycosuria of fat and of gouty people, and not less so in tendency to biliary concretions. In all these cases the beneficial effect is principally due to the washing out of the tissues or small ducts by the drinking of large quantities of water. The best known earthy or calcareous waters are: Wildungen, Lippspringe, Inselbad, Weissenburg, Contrexéville, Vittel, Bagnères de Bigorre, St. Arnaud, and Cransac; and among the table waters: Couzan, St. Galmier, and the Taunus water. In North America the best known earthy or calcic springs are: Butterworth Springs, Eaton Rapid Wells, and Leslie Well in Michigan; the Gettysburg Spring in Pennsylvania; the Sweet Springs in West Virginia; and the Alleghany Springs in Virginia.

Many of the waters mentioned in other classes might also be mentioned here, such as Bormio, Leuk, Bath, and Lucca, named under the simple thermal waters; and Baden in Austria, Baden in Switzerland, Schinznach, Battaglia, Abano, and others enumerated under the sulphur-waters.

On prescribing Mineral Waters and Baths.—In every case we must first settle the question whether the treatment by mineral waters and baths offers advantages over ordinary treatment. If the question is answered in the affirmative, we have to consider not only the nature of the disease, but quite as much the nature of the individual to whom it occurs; the amount of vital forces in general; the power of reaction; the state of the different organs; and whether they are healthy and vigorous and can assist in relieving the diseased part of the organism, or whether they are feeble or crippled and unable to respond to any unusual demand made on them. Thus we shall be enabled to decide whether stronger therapeutic influences can be employed; whether longer and rougher journeys are permitted, and colder climates and seasons; or whether delicate treatment is essential, comprising the simple thermal baths, summer temperature, mountain climates of moderate elevation, sunny aspects, and easy journeys. The baths and waters are not to be selected according to the chemical constitution of their springs alone, but the means

and appliances in use, and the accustomed methods of treatment at certain places, the qualities of the local physician, the accommodation, the food, the cooking, and the social conditions, the facility of reaching a place, the climate and other elements of 'change,' are each and every one to be taken into consideration. It must be evident already from these remarks that the same morbid affection can occasionally be treated with advantage by different classes of mineral waters and at different spas, and that apparently widely different diseases may be benefited by the same spa; not only because many mineral waters are composed of different active elements, but also because the internal and external administration of the same water may be so much varied as to produce a great variety of effects. In many instances the disease itself cannot be directly attacked, but our efforts must be directed towards improving the general constitution, and through this influencing the diseased portion of the organism.

In most cases the local physician is as important as the nature of the waters, and in some even more so.

We cannot do more here than give some hints regarding the groups of diseased conditions in which mineral waters may be prescribed.

1. *Anæmia.*—In cases of anæmia it is essential to consider whether the condition is caused, first, by direct loss of blood and its component parts; secondly, indirectly by acute or chronic disease, sleeplessness, neuralgia, and inability to take up food; thirdly, by congestion of the pelvic organs, with loss of blood and albuminous juices; or, lastly, by diseases of the lymphatic vessels and glands, or visceral affections resulting from malaria or hot climates or from habitual constipation. The more the first cause preponderates, the more we may expect from the direct use of iron; and we have then to consider whether treatment at home with pharmaceutical preparations, or iron-waters with or without change of climate, with or without baths, are to be preferred. In the indirect forms of anæmia the mildest thermal treatment, with mountain climates of moderate elevation, or the latter alone, with or without suitable medicinal treatment, are often the only beneficial courses in delicate constitutions; while in others somewhat less feeble according to individual conditions, common-salt waters and baths with or without iron, or the gaseous tepid salt-baths of Nauheim and Rehme, or the much stronger influences of sea-air and of sea-baths, are useful. In the third group the common-salt waters, with a certain amount of iron, and occasionally the sulphated saline waters, must generally precede every other attempt at strengthening; for the acceleration of the portal circulation, the regular emptying of the different branches of the portal vein, and the increased tissue-change are essential to the improvement of the nutrition and sanguification; and only after such a preliminary course the purer iron waters and the higher alpine air are likely to become useful. In the treatment of some forms of chronic tuberculosis muriated saline waters with sea-air and sea-baths are of considerable value.

2. *Sluggish Portal Circulation.*—A sluggish condition of the portal system forms a frequent complication, not only of anæmia, but of a great many ailments of the different systems of the body; and is often only a part of a general want of tone in the organic muscular fibre, especially of the right ventricle and of the whole venous system. It is difficult

to find a name for these, by no means rare, constitutional defects, which form the main characteristics of what the old German physicians called 'abdominal plethora.' If we only know what we mean by the terms, we may call these conditions *portal venosity* and *general venosity* according to the extent of the defect. They form the principal complications and in many cases the main cause of the most varied digestive troubles, as acidity, sickness, flatulency, constipation, and intestinal catarrh. They are also at the root of congestion of the hæmorrhoidal vessels and piles, of varicosity of the legs, of congestion of the womb and ovaries and menstrual anomalies, of congestion of the liver and imperfect secretion of bile, and of chronic bronchial catarrh, with dilatation and imperfect contraction of the right ventricle. Gravel and gout are likewise often associated with sluggish portal circulation. In the treatment of these very numerous complaints, widely different though they appear to be, we have therefore always to ask how far they are complicated by portal venosity, and how far diet, regimen, pharmaceutical and balneotherapeutic treatment directed against this venosity may relieve the special case before us. If this portal venosity occur in *lean and delicate* persons, the common-salt waters are often useful, as Kissingen, Homburg, Soden, Bourbonne-les-Bains, Salsomaggiore, the Saratoga Springs, Michigan Congress Spring, Spring Lake Well in North America, &c., which increase the tissue-change without impairing the nutrition, internally and in the form of baths, or the simple thermal baths in sub-alpine situations, assisted by the internal use of salt waters. If the individual be *stout* and inclined to costiveness, the sulphated saline waters with soda and common salt, such as Carlsbad, Marienbad, Franzensbad, Elster, Brides-les-Bains, Luhatschowitz, and Tarasp, are the most effective; while again in others of this class the simple alkaline waters, such as Vichy, the Congress Spring, &c., are preferable. In all these cases, however, the treatment by waters and baths ought to be assisted by regulation of diet and exercise.

3. *Gravel*.—Gravel, especially uric-acid gravel, is usually complicated with portal venosity, and is to be treated accordingly. As a symptomatic treatment, the alkaline mineral waters have a more lasting effect than the administration of alkaline pharmaceutical preparations; but more effective are alkaline waters containing sulphates, and especially the less concentrated and hot springs of Carlsbad. Most useful of all, especially for home treatment, are the waters of Luhatschowitz, with their peculiar combination of carbonates and chlorides. The earthy waters of Contrexéville and Wildbad have a historic reputation, and owe this in part to the large doses which can mostly be prescribed.

4. *Gout*.—Gout is likewise often complicated with and aggravated by a defective portal circulation, and we must always endeavour to facilitate the removal of the products of the retrogressive tissue-change; but gout occurs in the most widely different constitutions. If gout and its allied forms be met with in so-called strong constitutions, with a good primary digestion, ability to sustain a long morning fast, accompanied perhaps by a tendency to stoutness, and an acid urine of tolerably high specific gravity, becoming iridescent with nitric acid, the alkaline sulphated waters of Carlsbad, and sometimes those of Marienbad, Franzensbad, Elster,

Tarasp, and the muriated sulphated waters of Brides-les-Bains, are most useful, though they cannot altogether remove the gouty disposition. If the time be short, and a long rest after the course not permitted, the simple alkaline waters of Vichy may be selected, and in more delicate constitutions the muriated alkaline waters of Royat, Ems, or Baden-Baden. In lean and weak gouty patients, the common-salt waters of Homburg, Kissingen, and Leamington, the arsenical salt waters of La Bourboule, the waters of Wiesbaden, the muriated sulphur-waters of Aix-la-Chapelle, Harrogate, or Llan-drindod, or, again, weak muriated alkaline waters like Baden-Baden, deserve a trial. In many delicate persons the simple thermal waters of Buxton, Teplitz, Schlagenbad, Wildbad, Ragatz, Gastein, and Bath, and the sulphur-waters of Aix-les-Bains and Bagnères de Luchon, offer great advantages; but numerous cases may be regarded as quite intractable by baths and waters, and in these diet and climate and regulation of exercise are the only means of management, assisted by various anti-gouty medicines.

5. *Chronic rheumatism*.—In chronic rheumatism, associated with exudation round the joints, the hot thermal treatment is the most useful, either at the hotter simple thermal spas, as Bath, Teplitz, Acqui, the Euganean baths, the hot springs of North America, or the natural vapour-baths of the cave of Monsummano; at the weaker hot salt waters of Royat, Wiesbaden, and Baden-Baden; or at the thermal sulphur-waters, such as Aix-la-Chapelle, Uriage, Aix-les-Bains, Barèges, Bagnères de Luchon, and Eaux Chaudes. For more delicate cases, especially in those combined with weakness of the muscles of the heart, with or without valvular disease, we have the gaseous thermal salt waters of Rehme and Nauheim. In the muscular varieties, with stiffness, the hotter waters are specially indicated, assisted by douches and shampooing. In many instances, however, the cause of constantly recurring rheumatism is weakness of the skin, and here the tonic forms of the cold water-cure and sea-baths promise more permanent good than hot baths.

We might be expected to give a few hints on diet during mineral-water courses, but no general rules can be laid down. Every individual requires rules for his own case; and rules which may be necessary during the use of muriated saline or sulphated saline waters, are not necessary in other courses—for instance, of simple thermal or of iron waters.

The resident physician ought to guide every invalid, according to his or her individual condition, as well with regard to diet as to the internal or external use of waters, and with regard to exercise and other hygienic and therapeutic aids. The result of a course of waters often depends entirely on this guidance. It is important, therefore, to supply the bath-physician with a statement as to the ailments and the constitution of the invalid.

LENGTH OF TREATMENT.—It is a general belief that three or four weeks is the term for a course of waters or baths; but it is impossible to fix a definite time. As courses of iodide of potassium, of iron, of quinine, or of mercury must be of different duration in different individuals, exactly so we find it with mineral waters; and as two or three courses of a remedy may have to be taken in the same year, so it is often desirable to give two or three courses of Vichy, of Carlsbad, or of other Spa waters, in one year, though not all of them need be taken at the

spring. In many cases preparatory courses are advisable—climatic, medicinal, and balneotherapeutic; and in as large a number secondary courses. Most invalids ought not to return immediately after a course of baths to their usual abodes and accustomed ways of living, but ought to have what the Germans call a 'Nachkur,' at climatic health resorts selected according to the condition of each individual. In many instances, moreover, it is imperatively necessary to abstain from work, and to keep to a simple diet for about a month or more after the course of waters, and this is especially the case with the more powerful waters like Carlsbad and Marienbad. It must be clearly understood that, in order to make a course of waters permanently beneficial, it is necessary to avoid the injurious influences which have led to the morbid condition, not only for one or two months but for the whole life.

SEASON.—As to the period of the year, there is no time when the different waters might not be drunk, if it were necessary. Most spas are open only from May till October, some longer; some only from June till September; but some few localities are partially open also during the winter, especially Aix-la-Chapelle, Aix-les-Bains, Dax, Amélie-les-Bains, Bath, Acqui, Salsomaggiore, Baden-Baden, and Wiesbaden. Many waters can be taken at home, and at any time of the year; but when taken at home the elements of change are wanting, and the strict adherence to regimen and diet is often difficult. During the summer months the demands on the human body are diminished by the external warmth and the greater equability of the meteorological influences; nature is more exhilarating, and invites to outdoor life and exercise, without much risk of chills and their consequences. Delicate persons, therefore, ought to select the summer months for courses at the spas. The later parts of the spring and the autumn, however, offer advantages to the more robust, who at those times find the baths and the hotels less crowded, and who can then receive more attention from the bath-physician. And, besides, those who are unable to bear heat have in the earlier and later parts of the season the benefit of cooler air, which is to the average visitor a real advantage at some of the hotter localities, like Aix-les-Bains, Acqui, Salsomaggiore, Aix-la-Chapelle, Ems, Kreuznach, Wiesbaden, Soden, Baden-Baden, and Ragatz. MISCARRIAGE.—SYNON.: Abortion; Fr. *Avortement*; *Fausse Couche*; Ger. *Fehlgeburt*.

DEFINITION.—Miscarriage is the interruption of gestation before the fœtus has become viable.

FREQUENCY.—The relative frequency of miscarriages, of premature labours (between the seventh and ninth months), and of full-time births, cannot be very closely estimated. Early abortions are often unnoticed or forgotten. The statement of Whitehead is very striking, that of sixty-four women

who had lived in wedlock till the menopause, there were only eight who had not at some time had a miscarriage. His statistics show that the period at which abortions most frequently occur is about the third month.

ÆTIOLOGY.—The causes of abortion may be found either: (1) on the part of the ovum or fœtus; or (2) on the part of the mother.

1. *Fœtal.*—The causes of miscarriage on the part of the ovum are: (a) all the diseases of the fœtus itself which compromise its life, such as acute fevers and chronic diseases—chiefly of syphilitic origin; and (b) many of the morbid changes in the fœtal appendages. Of the latter the most noteworthy are, first, diseases of the chorion, the most familiar of which is the hydatidiform degeneration; secondly, abnormal conditions of the umbilical cord, such as excessive torsion with constriction of the vessels, convolutions of it simultaneously round the neck and lower extremities, and the formation of tight knots upon it; and thirdly, abnormal relations and morbid conditions of the placenta. Where the placental area, for example, is of too limited extent, the ovum easily becomes detached from the uterus; where it is too large, extravasations of blood easily take place in the lobules. When the placenta is planted low down in the cavity of the uterus, it is liable to partial detachments; and thus in a great many cases abortion takes place at an early stage in patients who would have been subject to the greater dangers of unavoidable hæmorrhage had the pregnancy gone on towards the usual term. Again, the morbid processes which occur in the placenta, inflammatory, degenerative, or apoplectic, whether due to a syphilitic taint, or to other causes, lead to death of the embryo or fœtus, and thus in many instances to the early casting of the ovum. It is worth while to note that death of the embryo, and morbid changes in its appendages, do not necessarily at once cause abortion. Three or four weeks usually elapse after the death of the fœtus ere its expulsion is effected; the decidual membrane having in the interval undergone retrogressive changes. It is only when such an extravasation of blood takes place as leads to sudden distension of the uterus, or when the membranes burst and such escape of liquor amnii occurs as leads to its sudden collapse, that the organ is stimulated to the immediate evacuation of its contents. Hence, while the ultimate cause of abortion is often enough traceable to the ovum, the immediate occasion is more frequently due to some maternal condition.

2. *Maternal.*—The causes of miscarriage on the part of the mother are either (a) *general*; or (b) *local*. (a) Among the *general* or constitutional conditions that favour the occurrence of abortion we note, first, all the causes that lead to depression of a woman's health. Abortions are frequent, for instance, in times of famine; among women who yield themselves to excesses; in anæmic women; and in those tainted with the syphilitic poison. Often enough, especially in the last class, the cause of the abortion can be traced to some morbid change in the maternal portion of the placenta; but sometimes it seems to be due simply to the impure or impoverished condition of the patient's blood. Secondly, fevers, such as the zymotic fevers, and acute inflammations, more particularly of important viscera, such as pneumonia, occurring in gravid women, very frequently become complicated by abortion. Thirdly, shock may bring on mis-

carriage, whether operating simply through the nervous system, of which we meet occasional examples, or, as is more frequently the case, by producing a more direct physical impression upon the uterus, as in cases where the patient leaps or steps suddenly down from a height, lifts a weight, stretches her arms above her head, or is exposed to any sudden jar or more protracted jolting. Though many cases of abortion are attributed to such a cause, it is always to be borne in mind that in some of these, at least, the supposed cause would not have led to the disaster unless there had already existed a predisposition in some morbid condition of the uterus or its contents.

Among (*b*) the *local* causes we find, first, and most frequently, diseased conditions of the deciduæ. Commonly in these cases the patient had previously been the subject of chronic endometritis; though occasionally cases are met with where there have been no marked symptoms previously, and the degenerative process may affect either the vera or reflexa or serotina, separately or simultaneously. Second in frequency under this head we have the abortions due to displacements of the uterus, these being commonly either descents or retroversions. Thirdly, neoplasms of the uterus, such as cancers or fibroid tumours, sometimes permit the occurrence of conception, but prevent gestation running to its natural term. Fourthly, the presence of tumours in the neighbouring organs, or inflammatory adhesions among them, may prevent the uterus from attaining its full growth, and compel it to early evacuation of its contents.

SYMPTOMS AND DIAGNOSIS.—In dealing with a case of suspected miscarriage, we have to determine first that the patient is pregnant. This we do by a careful inquiry into the patient's history, and a complete physical examination. Supposing that, by the usual investigation into the signs and symptoms of pregnancy, we are satisfied that gestation had begun, we have next to ascertain whether miscarriage is only threatening to come on, has fairly set in, or has already been completed.

The symptom that, in the great run of cases, first attracts attention, which usually goes on till the process is completed, and which continues for some hours or days subsequently, is hæmorrhage. The amount of blood lost varies indefinitely; and so does the manner of its escape. In certain cases the onset of pelvic pains, with the regular intermissions that betray their origin in the muscular contractions of the uterine walls, alarms the patient and attracts her attention before any escape of blood has taken place. These cases are exceptional. Usually the hæmorrhage precedes—and it may be for days or weeks—the expulsive action of the uterus. The cases, however, are rare—unless they be instances of very early abortion—where the process is completed without the accession of appreciably painful contractions. Occasionally there occur discharges of liquor amnii or other watery fluid, or of fragments of the degenerated membranes, or of the disintegrated foetus.

These symptoms call for physical exploration of the uterus. If we find the uterus gravid, with the os undilated and the cervical canal above it unexpanded, the hæmorrhage being slight and the pains controllable, we regard and treat the case as one simply of threatened abortion. But if the pains are persistent, if the os uteri opens to admit the finger, or the canal of the cervix above it is becoming ex-

panded; still more, if the uterine contents are being pressed down within reach of the exploring finger, we have to do with an actual abortion which it is useless to seek to avert. The treatment of actual abortion is often enough called for, even with quiescent uterus and closed canals, when the hæmorrhage is profuse.

In trying to determine whether the miscarriage is completed, we have first to examine the mole or mass that has been expelled. This consists sometimes of the ovum alone; of the ovum and decidua reflexa; or of the ovum with all the uterine deciduæ. Where the uterine contents escape in broken-down fragments, and cannot be satisfactorily pieced together, it becomes necessary to examine the uterus, and even to explore the interior of that organ with the finger; and in these and other cases where the diagnosis is doubtful, it may be requisite sometimes to dilate the cervix with a carbolised sponge or tupelo tent, or with Hegar's dilators, in order to get full access to the uterine cavity.

TREATMENT.—The treatment of miscarriage varies according as we have to do with a case of (1) threatening abortion; or (2) abortion in actual progress; or (3) incomplete abortion.

1. *Treatment of threatening abortion.*—The treatment in a case where abortion is merely threatening is largely expectant. The patient is put to bed, and kept at rest in the recumbent position. All exercise or excitement, physical or psychical, must be forbidden. A light, non-stimulating diet, with fluids for the most part cold, is to be enjoined; and any tendency either to constipation or to diarrhœa is to be combated. Where the hæmorrhage is continuous and the uterus atonic or flaccid, small doses of ergot—twenty drops, every six or eight hours, of the liquid extract—are useful. Diluted sulphuric acid or gallic acid, either alone or in combination with digitalis, may be administered. Where there are occasional pains accompanying the discharge, the best effects are obtained from the administration of opiates, which may be prescribed in the form of the acetate of lead and opium pill. Where the pains constitute the more urgent symptom, and the hæmorrhage is less, it may be well to check the uterine action at once by the use of an anæsthetic followed by opiates, or the administration of a dose of chloral hydrate; and the astringent may then be dispensed with. The opiates in such cases are best administered hypodermically or *per rectum*. In many cases the liquid extract of *Viburnum prunifolium* in doses of ʒss–ʒi has proved useful as a sedative to the uterus in threatened abortion.

2. *Treatment of actual abortion.*—Where the stage of expectancy is clearly over, and the patency of the os internum, the persistence of the pains, or the profusion of the hæmorrhage, calls for active interference, there are two main indications to be fulfilled—namely, to restrain the hæmorrhage; and to ensure the complete evacuation of the uterus.

To restrain the hæmorrhage, we compel the uterus to more energetic contraction, first, by the administration of large repeated doses of ergot. A drachm of the liquid extract may be given every three or four hours; but the effect of the drug can be most speedily and safely ensured by the hypodermic injection of ergotin—according to some such formula as this: ℞ Ergotini ʒij ; $\text{chloral hydratis ʒss}$; $\text{aquæ destillatæ ʒvj}$ —16 drops to be injected into the gluteal muscle (*see HYPODERMIC MEDICATION*). The dialysed solution of ergotin is said

to produce less irritation. Secondly, the genital canal must be plugged. Where we have no other means at command of checking the discharge, a carefully applied vaginal tampon may be trusted; or the vaginal plug may be used where the hæmorrhage is going on but there is still some hope that the abortion may be arrested. Where the indication is more urgent, the introduction of a sponge tent into the cervical canal is very much more satisfactory, and in every way more efficacious. It arrests the hæmorrhage immediately and inevitably; it excites the uterus to more energetic action; and it at the same time expands the cervical canal in all its length. Where the indication is present for still more rapid dilatation of the cervix, this may be effected by means of dilators, such as Hegar's.

The complete evacuation of the uterus may take place by the unaided efforts of its muscular walls. On visiting a patient in the morning, who had a sponge-tent passed into the cervix uteri and a hypodermic injection of ergotin over night, we may find sponge and ovum and all expelled. Where the ovum is still *in utero*, if it be loose and the cervix dilated, compression of the uterus from above the pubes may suffice to make it expel its contents. Usually, however, it becomes necessary to get at the interior of the uterine cavity with a finger or fingers passed through the vaginal canal. In most cases it greatly facilitates the operation to anaesthetise the patient, and in some cases the previous administration of chloroform is absolutely necessary. To render the uterus accessible to the exploring fingers, it must either be pushed down from above or dragged down from below. The patient lying unconscious on her back, the fundus uteri may be depressed by the left hand pushed firmly and steadily down through the pelvic brim. The depression may be effected by an assistant, but never so satisfactorily as by the operator himself. No less than two fingers of the right hand should be used for the internal manipulation; the middle finger being folded in the fornix vaginae, while the index passes through the os to the fundus uteri, and sweeps round the entire ovum, detaching it at any adherent points. Sometimes the middle finger more conveniently enters the uterine cavity; and in most cases of miscarriage in the fourth month, the whole hand, except the thumb, may require to be passed into the vagina, and two or more fingers into the uterine cavity. Even where the vaginal orifice is not at first very wide, if the hand be carefully warmed and soaped, and the interstices of the fingers filled up on their palmar aspect with a quantity of half-melted soap, sufficient dilatation is speedily effected. Occasionally the smaller left hand may be employed for internal manipulation, while the stronger right is engaged in making the external pressure on the fundus uteri. Access to the interior of the uterus may in most cases be gained more easily by dragging the uterus down from below. One or other of the lips of the uterus—usually the anterior—is seized with a vulsellum, double- or triple-pronged, and slightly curved. One of the blades grasps the vaginal aspect of the front lip of the cervix as high up as the roof of the vagina, the other at a corresponding level within the cervical canal. The uterus is capable of being drawn far down without any injury to its ligaments, or any laceration by the bite of the vulsellum. It may be pulled down with the right hand and kept fixed by it, while the fingers of the left pass into the cavity, and explore and evacuate it. Or the vulsellum may

be held in the left hand, or given to an assistant, to keep the uterus depressed, while the more familiar right-hand fingers do the intra-uterine work. The finger or fingers that have detached the ovum commonly succeed in extracting it, aided sometimes by pressure with the other hand from without. If not, there is no objection to laying hold of the loosened body with a pair of long dressing-forceps, or a Lyon's or polypus-forceps, and so withdrawing it; but no such instrument, even though it bear the name of abortion-forceps, ought to be trusted to for the detachment of a retained ovum or fragment of adherent placenta. The separation should always be effected by the direct action of the living finger.

3. *Treatment of incomplete abortion.*—In mismanaged cases the uterus is left imperfectly evacuated, and the patient continues to suffer from menorrhagia and metrorrhagia—it may be for months subsequently. In such circumstances the use of the curette is invaluable. Sometimes a degree of dilatation with tupelo tent or otherwise is required, but usually the cervical canal easily permits of the passage of a curette, with which the surfaces of the uterus can be scraped and the entire cavity of the organ can be cleared out. The curetting should be accompanied or immediately followed by the washing out of the cavity with a stream of hot water, of the temperature of 110° to 120° F., containing 1 in 5,000 of corrosive sublimate, or some such antiseptic, with the view at once of checking further hæmorrhage and disinfecting the uterine cavity. In the cases where the ovum has undergone hydatidiform degeneration, the further progress of the patient should be watched with special care. In a number of women who have been the subjects of such a 'molar pregnancy,' malignant degeneration has taken place in the interior of the uterus, apparently from the retention of some of the chorionic elements. This *deciduoma malignum* may give rise to fatal hæmorrhages or to metastatic processes in the lungs and other organs; and the patient's only chance of cure is obtained by an early hysterectomy. See PLACENTA, Diseases of.

After-treatment.—The uterus having been completely emptied, the patient should be kept at absolute rest in bed, and subjected to the same treatment as an ordinary puerperal female.

ALEXANDER RUSSELL SIMPSON.

MITOSIS (μῖτος, a thread).—SYNON.: Karyokinesis; Indirect Cell-division.—The process by which living animal-cells usually divide and multiply. See CELL.

MITRAL VALVE AND ORIFICE, Diseases of.—See HEART, VALVES AND ORIFICES OF, Diseases of.

MOFFAT, in Scotland.—Sulphur and also chalybeate waters. See MINERAL WATERS.

MOGIGRAPHIA (μόγισ, with difficulty; and γράφω, I write).—A synonym for writer's cramp. See WRITER'S CRAMP.

MOLE.—**MOLAR PREGNANCY.**—DEFINITION.—A degenerated mass formed in the uterus as a result of conception.

There are two varieties of mole: (1) the fleshy, carneous, or blood-mole; and (2) the vesicular or hydatidiform mole.

1. **The Carneous or Fleshy Mole.**—This is sometimes called a *blood-mole* or *apoplectic ovum*

owing to its hæmorrhagic origin. Some authorities think that a *carneous mole* is a later stage of a 'blood-mole,' altered either by organisation or by changes due to decidual endometritis. The carneous mole is due to hæmorrhage into the decidua vera or serotina. The blood may find its way between the decidua vera and reflexa, or between the chorion and amnion, or more rarely may invade the amniotic cavity itself. In any case the involved chorionic villi are separated from the maternal blood-supply, or rendered useless by compression, and if the hæmorrhage be extensive, or be in the neighbourhood of the insertion of the cord, the embryo perishes, and shrinks, and, if the amniotic cavity is encroached upon, may disappear altogether. The resulting mole is a thick-walled cyst, lined by amnion, which is thrown into irregular bosses by the extravasated blood. It is distinguished from extruded fibroids by its general appearance and by the presence of decidual cells and villi, and by the absence of muscle-fibres. From the membrane of membranous dysmenorrhœa, and from the decidua of ectopic gestation, it is distinguished by the presence of villi and by the great thickness of the cyst-wall. A mole of a similar type may form in the Fallopian tube in cases of tubal gestation. See PREGNANCY, Diseases of.

SYMPTOMS AND DIAGNOSIS.—After a few weeks of pregnancy the usual symptoms and physical signs of gestation gradually become less defined. If the uterus be examined bimanually at intervals during this period, it is found to have become suddenly enlarged as a result of the hæmorrhage, and then to have gradually lessened in size, remaining smaller and more incompressible than it would have been in normal pregnancy. The ovum may at once come away, or, as frequently happens, may remain *in utero* (*missed abortion*) till the fifth or sixth month; or even remain, a fact of medico-legal importance, till long after full-term, and cases are reported where menstruation has in the interval been normally re-established. More usually, however, there is a brownish and sometimes offensive discharge, with occasional bright red hæmorrhage, and the diagnosis then has to be made (1) from the hæmorrhage caused by decidual endometritis, when the uterus is usually normal in size and evidences of normal fetal growth are forthcoming, (2) from hydatidiform degeneration of the chorion to be presently considered, and (3) from deciduoma malignum (see PLACENTA, Diseases of; and PREGNANCY, Diseases of), or (4) from a normal pregnancy with such complications as epithelioma, or mucous polypus of the cervix. The differential diagnosis will be discussed under the next variety.

TREATMENT.—The treatment is to empty the uterus. While the mole remains in its cavity, the patient is exposed to the risks both of hæmorrhage and of septic infection. The administration of ergot may be sufficient to stimulate the uterus to expel its contents; but should this not occur, the aseptic use of the sound will often succeed. Should the uterus still remain inert, the cervix must be dilated rapidly, under anæsthesia by preference, and the contents removed by the finger or by ovum-forceps, aided by supra-pubic pressure; and the cavity washed out with some warm antiseptic injection, and lightly packed with iodoform-gauze for twenty-four hours.

2. The Vesicular or Hydatidiform Mole. The term 'hydatid mole' is misleading, as the condition has nothing to do with the *Tania echinococcus*.

ÆTIOLOGY.—The ætiology of these moles is still obscure. They are known to be secondary to fertilisation of the ovum, though a few authorities have endeavoured to prove that it may occur in the uterus of a virgin; it is the cause and not the result of the death of the embryo; it may occur in successive pregnancies in the same woman, and yet may in other cases be found in only one of twins; it may exist in cases where both the mother and child have been dropsical; it occurs with greater relative frequency in woman after thirty years of age; and though there may be no history of syphilis in the woman herself, it is not infrequently found in women whose husbands have had that disease.

MORBID ANATOMY.—The vesicular mole is the result of a myxomatous degeneration of certain of the cells forming the inner lining of the chorionic villi. These cells swell and gradually fill up the cavity of the villus, giving it the appearance of a vesicle, and causing obliteration by pressure of the contained loop of capillaries. This degeneration occurs at intervals along the length of a chorionic villus, giving it a moniliform appearance like a series of vesicles threaded on a fleshy stalk. The disease may be confined to those villi which usually atrophy during the second and third month, or may affect mainly or exclusively those engaged in forming the foetal portion of the placenta. The depth to which the vesicles penetrate into the uterine decidua or even into the muscular tissue depends upon the depth to which the villi had already penetrated. The embryo, in its compressed or obliterated amniotic cavity, is rarely discovered, unless the affected villi cover only a small area.

SYMPTOMS.—After four or five weeks of apparently normal pregnancy the patient notices a little hæmorrhage at irregular intervals, often induced by stooping, lifting, coitus, or straining at stool. The hæmorrhage is, as a rule, slight and watery. Occasionally, if villi are detached from the decidua, hæmorrhage may be profuse, and if vesicles protrude through a dilated cervix, the discharge may become brown and offensive. As a rule the constitutional (reflex) symptoms of pregnancy, such as morning sickness, are more marked and more persistent. The physical signs differ from those of normal pregnancy in that the size of the uterus increases at a greater rate owing to the vesicular growth, and that although intermittent contraction of the uterus and the uterine souffle are observed, the evidences of the presence of a foetus, such as abdominal and vaginal ballotement, foetal movements, and foetal heart-sounds, are absent, except in those rare cases when a second normal foetus is also present.

A vesicular mole may be expelled at any period of gestation, or it may remain and be expelled at an indefinite date after full term.

DIAGNOSIS.—The diagnosis has to be made from normal pregnancy by the hæmorrhage and by the physical signs as already stated. It has also to be distinguished from those cases of pregnancy accompanied by hæmorrhage due to decidual endometritis, or to such complication as mucous polypus or malignant disease of the cervix; as a rule, the fact that in these conditions the uterus is not larger than the size expected for the date serves to make the diagnosis. In case of fleshy mole the uterus is smaller than it would be if a normal pregnancy, and this at once distinguishes the case from that of a vesicular mole, when the uterus is much larger than

normal, reaching the level of the umbilicus at the fourth month. A certain diagnosis can, however, often only be made by discovering vesicles in the discharge, or by dilating the cervix and exploring the uterine cavity. This, for instance, is the only way to differentiate between vesicular mole and deciduoma malignum, and in this connection it must be remembered that cases have been recently reported of new-growths of a similar myxomatous type, apparently growing from tufts of myxomatous villi left in the uterine wall, with secondary growths in the labia majora and lungs.

TREATMENT.—As soon as the hæmorrhage and physical signs have led to a positive or tentative diagnosis, the uterus should be encouraged to expel its contents by drachm-doses of the liquid extract of ergot three times daily, and the patient should use, twice daily, an antiseptic vaginal douche.

If the mole still remain *in utero*, and hæmorrhage persists, the patient should be anæsthetised, the cervix dilated rapidly with graduated bougies, and the uterine contents carefully separated by the exploring finger combined by external manual pressure. This method of 'expressing' the uterine contents while the internal fingers gently separate and extract the vesicles as they come within reach is far the safest plan, for the uterus is so easily lacerated in these cases that the use of the curette is fraught with danger. The uterus should then be irrigated with iodised water and lightly packed with gauze, the patient kept in bed for ten days, and ergot given to encourage involution. Great care should be taken to detach all vesicles, otherwise secondary hæmorrhage or septicæmia are possible complications.

It is important to remember that twin pregnancies may occur in which vesicular degeneration affects the chorion of but one ovum; and that quite possibly the sound ovum may proceed to full development, as is said to have occurred at the birth of the anatomist Beclard.

AMAND ROUTH.

MOLES.—This term is applied to a circumscribed pigmented spot or tumour of the skin, of developmental origin, frequently raised above the surface, roughly papillomatous in structure, and often with an excessive development of hair. Occasionally moles develop in later life, but in such cases the lesion is probably due to some defect during development, which has escaped notice. Subsequent increase in size draws attention to the affected area. Areas of abnormal pigmentation with overgrowth originate from various causes in later life, and to such lesions the word 'mole' is also applied, but they pass, strictly speaking, into a different category. To these congenital defects the term *nævus* is also frequently applied.

Such a mole or *nævus* may consist simply of an excess of melanin deposited in the lowest layers of the stratum mucosum and in the limiting layer of the cutis, and such pigment-spots especially develop at any period of life. But usually the abnormalities of development are more marked. Thus irregularities in the growth of the cutis may produce irregularities of the surface, and lead to the formation of papillomatous excrescences (*nævus verrucosus*, *nævus papillomatosis*). More important are the apparently isolated inclusions of epithelium, which lie deep in the connective tissue. These epithelial inclusions are the areas which probably first show the signs of overgrowth and malignant change, not

infrequently arising in moles. Hairs are usually present on the surface, and may be fine and lanugo-like, or more usually numerous and firm in consistence (*nævus pilosus*). The changes in the connective tissue consist of increase in amount, abnormal development of blood-vessels (*angiomata*), and occasionally excessive formation of fat-cells. The amount of pigmentation is usually great, but it may be only slight, or even in some cases apparently absent (white moles).

The distribution and size of moles vary within wide limits. They may be quite small or occupy large areas of the surface; and occasionally the skin of a limb or of a large segment of the body may develop the *nævus* structure. A linear distribution along the course of a limb, or on the trunk, may sometimes be seen, suggesting the distribution of the cutaneous nerves, but are probably so arranged owing to defects in the development of the body-segments (*nævus unius lateris*).

Small moles give little trouble, but when large and disfiguring, or interfering mechanically by their presence, they should be removed. This should be done thoroughly by excision, and care should be taken to irritate the affected areas as little as possible. In the case of small moles destruction by electrolysis is possible, and the electrolysis of the hairs on a mole is occasionally sufficient to destroy the whole structure. Irritation and attempted destruction by caustic agents are inadvisable, especially in the case of adults. Growths originating in moles are usually melanotic, and often of great malignancy. It cannot be doubted that tampering with moles by means of irritating agents is likely to stimulate the tendency shown by these formations to become malignant.

JAMES GALLOWAY.

MOLLITIES OSSIUM (Lat.).—SYNON.: Osteomalacia; Malacosteon; Fr. *Ramollissement des Os*; Ger. *Knochenerweichung*.

DEFINITION.—A condition characterised by a progressive decalcification of the bones and replacement of the true bone-tissue by a soft very vascular gelatinous material, and leading to great deformity of the skeleton.

ÆTIOLOGY AND PATHOLOGY.—The disease is rare, and much more rare in Great Britain than on the Continent. It chiefly attacks the poor, and is ten times more frequent in women than in men. It is most often met with between the ages of 25 and 35, and pregnancy appears to exert a marked influence in causing the disease. Thus, among women, it is almost limited to multiparæ, and many of the patients have borne children in rapid succession. The symptoms are usually first observed during pregnancy, and the disease may be arrested after parturition and become again active on the recurrence of pregnancy. The removal of the uterine appendages is said to have had a beneficial effect upon the disease. The lime-salts of the affected bones are dissolved by lactic acid, and the disease has therefore been attributed to an excess of this acid in the blood. The occurrence of many cases in certain localities has led to the suggestion that there may be some climatic condition causing the disease, and that it may be endemic. The *vera causa* of this affection is at present unknown. It is not an inflammatory disease of the bones, nor is it a true atrophy such as occurs from disuse, or old age, or in mental and malignant disease, nor can it be described as a neoplasm. It

appears to have no connection with rickets, which is a change in growing bones, whereas mollities ossium attacks the fully-formed skeleton. It is a disease *sui generis*, commencing in the medulla of bone and gradually extending thence to the periphery. Whether it is due to the presence of excess of acid, such as lactic acid, in the medulla, or whether this is one of the effects of a more subtle nutritive change is not determined.

ANATOMICAL CHARACTERS.—The osseous lamellæ become decalcified progressively from the centre towards the periphery of the bone; for a short time after this the lacunæ and the contained corpuscles can still be made out, but gradually all trace of the bone is lost, its place being taken by a very vascular soft gelatinous tissue which has previously replaced the true marrow. Into this soft fibro-cellular tissue hæmorrhages often occur; in extreme cases it may be almost diffluent. The outer shell of bone is the last to be affected, and in advanced stages of the disease this may be perforated in several places. There is no change in the periosteum, nor any formation of new bone beneath it.

As the result of this process the bones become very soft and yield under the influence of gravity and muscular tension, so that the most extreme deformities result. The change first affects the bones of the pelvis and the lower part of the spine, and the disease is often first recognised during parturition. The deformity produced in the pelvis is great and peculiar; the sacral promontory falls forward under the weight of the body, the pubic symphysis is forced forwards like a beak, and each acetabulum is pressed in by the head of the femur. This 'beaked' or 'triphite' pelvis may be the cause of serious difficulty in parturition. Next to the pelvis and spine the ribs are the bones most often affected; numerous fractures and bendings may occur, and the most characteristic change is the formation of a deep vertical groove on each side due to the pressure of the arms; the ribs are often broken at the front and back of this groove. Multiple fractures as well as bendings occur in the long bones of the limbs; in the earlier stages the fractures may unite, but when the disease is advanced union does not occur. Osteomalacia attacks fully-developed bones, and does not begin in, or chiefly affect, the epiphyseal ends of long bones. Excess of lime-salts is present in the urine and fæces, the channels by which the absorbed salts are eliminated.

SYMPTOMS.—The onset of the disease is very insidious; the patients are usually thin, anæmic, and poorly nourished. Pain of a 'rheumatic' character is generally experienced, but as this is referred to the pelvis and lower parts of the spine, and usually accompanies pregnancy, it is often supposed by the patient and her friends to be connected with the enlarging uterus. It therefore happens that as a rule no special attention is paid to these pains, and only when parturition commences and an examination is made are the grave effects of the disease discovered in the narrowed distorted pelvis which gravely interferes with natural delivery. Similar rheumatic pains are felt in other affected bones, and the bones may appear to be slightly enlarged; they are tender to pressure. But here also it is only when the bones are found to be softened so that they yield to pressure in various directions, or can be bent by the surgeon, or undergo numerous spontaneous fractures, that the nature of the disease is recognised. The disease is

chronic; it is very rarely arrested altogether; sometimes the condition seems to improve for a time, more generally the patient slowly becomes more and more crippled, deformed, and helpless, and finally succumbs from some intercurrent disease, especially of the respiratory organs, whose function is gravely interfered with by the softening and fractures of the ribs and sternum. Many of the patients have lost their life during parturition from the severe procedures necessary to effect delivery.

DIAGNOSIS.—The age of the patients affected, the bones first attacked, and the extreme softening that occurs in them, at once distinguish this disease from rickets. Some authorities have described a form of mollities ossium occurring in adolescents, but it is very doubtful whether this differs essentially from late rickets. The extreme softening and bending of the bones, the early and special affection of the pelvis and spine, followed by the wide extent of the changes in the skeleton, and the age and sex of the patients, are the points which serve to distinguish mollities ossium from fatty atrophy and spontaneous fracture from malignant growths or so-called fragilitas ossium.

TREATMENT.—As soon as the disease is discovered, everything possible should be done to improve the general nutritive condition of the patient. She should be removed to a bracing locality—certainly removed far from any district where the disease is endemic—and supplied with a liberal nourishing diet. Careful gentle massage may usefully replace the exercise which has become impossible. If pregnant, abortion should be induced. Future pregnancy must be forbidden. Some good has been reported to follow oophorectomy. If delivery at term has to be effected through the abdominal wall, the uterine appendages should certainly be excised with or without the uterus. The administration of bone-marrow in tablets has been followed by benefit, and appears to be a hopeful method of treatment. A. PEARCE GOULD.

MOLLUSCUM CONTAGIOSUM.—**SYNON. :** Epithelioma contagiosum.—This disease is characterised by the growth of small contagious tumours from the epidermis.

DESCRIPTION.—The tumours vary in size from the smallest visible spot to that of a pea. Very rarely larger masses have been produced by the confluence of smaller ones. They project from the surface of the skin in a distinctly hemispherical form and have a firm elastic consistence. They are often semi-translucent and have a yellowish or 'mother-of-pearl' tint varying to some extent with the texture and pigmentation of the surface which they occupy. Early in the course of their growth they present a depression on the summit which, as the tumour increases in size, is seen to be the orifice of a passage leading to a cavity in the centre of the tumour occupied by epithelial debris, due to degeneration of the epithelial cells composing the tumour. From this orifice the degenerated cells escape or can be expressed as a greyish-white caseous material. Occasionally more than one channel may lead to the softened centre of the tumour. The tumours arise on any part of the skin, but are most frequently observed on parts exposed to contagion. Thus the face, especially in the case of children, is one of the commonest sites. In adults the genital organs and surrounding parts are not infrequently affected, and the breasts in the

case of nursing women may become inoculated. In rare cases the tumours may be scattered over the whole surface of the body. The tumours increase slowly, frequently taking months to attain their full size, and then remain without much alteration for an indefinite period. Slight injuries cause their destruction. They not infrequently suppurate, and may then be a source of much pain and inconvenience; but their tendency is to wither away or to disappear from some accidental injury. Scars do not remain unless suppuration has occurred or they have been removed by violence.

CONTAGION.—That the disease is contagious is shown by the following evidence: (1) Many well-authenticated instances are now recorded of the disease spreading from one individual to another. One child after another in a family becomes affected, and nurses communicate the disease to children under their charge. One of the most interesting examples of conveyance of the disease from one individual to another is given by Neumann. A group of cases consisted of a mother and twins—infants at the breast. The disease showed itself in one of the infants, the mother's breast was then affected, and, finally, the other child showed the disease. (2) Outbreaks of the disease in hospitals and schools have frequently been placed on record. (3) Instances are recorded of physicians and others accidentally inoculating themselves by contact with cases of the disease. Brocq is quoted by Stelwagon as follows: 'I inoculated myself involuntarily with molluscum with my nails, after having pressed out with the nails of the two thumbs the contents of a lesion of molluscum in a patient. Soon afterwards I inadvertently scratched my face. About a month and a half later several lesions of molluscum developed in this region.' (4) Many attempts have been made to inoculate the disease experimentally, and though in the majority of the instances the experiment has failed, enough successful inoculations have been recorded to establish its possibility. The exact nature of the contagion is unknown. The incubation-period seems to vary from four weeks to six months, the usual period being from six weeks to three months.

It is worthy of remark that certain animals, especially birds, e.g. pigeons and domestic fowls, suffer from a disease affecting the head, beak, and claws very similar in appearance to molluscum contagiosum, which has been described as *epithelioma contagiosum* of birds. Cases have been described of persons handling animals so affected who presented lesions resembling those of molluscum contagiosum.

HISTOLOGY.—Recent observations show that the tumours do not arise from the sebaceous glands, as was formerly supposed. The increase in the cells takes place in the rete Malpighii, at one point or at several points in close vicinity. The mass of new tissue pressing downwards tends to flatten the underlying papillae, although some of them may remain and serve to form the fine fibrous partitions which separate the lobules of the growth from each other. The overlying epithelium becomes raised and stretched, and the pressure thus produced serves to retain the little lobules of the tumour in close contact with each other. As the tumour increases in size, one or more depressions or umbilications appear on the surface, due to falling inward of the most projecting point of the growth, and then the mass of newly-formed epithelium below appears to be in continuity with, and invaginated from, the over-

lying epithelium. On examining the interior of the growth the cells of the rete are seen to be large, but may seem normal in other respects, showing their 'prickle-systems' as in the normal skin. The stratum granulosum is present, and usually more developed than usual. Its cells retain a regular arrangement till degeneration of the epithelium occurs, when slight injury readily causes them to become displaced. The keratinisation of the epithelium occurs normally; but it is noted that the cells of what should form the horny layer do not shrivel in the usual way, but remain large and become more and more distended. This distension is due to the appearance of a peculiar colloid or hyaline degeneration of the protoplasm of the cells, which may be noted in the cells of the stratum mucosum, but becomes more obvious as the horny layer is reached. As the cells become distended with the material, they produce certain peculiar microscopic appearances, owing to the distribution of the colloid substance within the cells, which have been recognised for long as the 'molluscum-bodies,'—the cells in the horny layer becoming completely distended, showing almost no trace of their nuclear chromatin, and resembling small cysts. Some observers have affirmed that these bodies are intracellular protozoa. But none of the signs of reproduction have been satisfactorily observed in the molluscum-bodies. They have not been grown externally to the body; and therefore no successful inoculation from a pure culture has been made. The hypothesis that these 'molluscum-cells' show protozoal infection can therefore no longer be sustained.

As the horny cells form they lose their 'prickle systems' and become less adherent to each other. At the same time the hyaline degeneration of their protoplasm renders them soft, so that pressure on the tumours causes the internal degenerated mass to become expressed as the 'curdy' material so easily recognised. At or near the surface of the tumour, intermingled with the molluscum-cells, various bacteria may be recognised. Their presence is accidental, but explains the ease with which suppuration may arise.

TREATMENT.—The injury done to the tumour by expressing its degenerated contents is frequently sufficient to cause it to shrivel and disappear. The introduction of a drop of pure phenol, acid-nitrate of mercury, or of a sufficiently strong solution of iodine, by means of a glass rod or a spill of hard wood, is, however, a more satisfactory method of destroying the growth. Often the most satisfactory method of treatment is to split the small tumours to their bases with a suitable sharp knife, empty the contents by means of a small curette, and then control the small amount of hæmorrhage likely to ensue with a pad of lint and bandage, or with a collodion-gauze dressing. Suppuration is apt to be caused, and should be avoided with care. Occasionally it is wise to excise the tumour entire, so as to produce a 'clean cut,' especially when suppuration must be rigidly avoided, as in the neighbourhood of the orbit. Electrolysis is of considerable service in destroying the tumours when they occur in situations rendering an incision inadvisable. In cases where small tumours are present closely aggregated on the trunk or extremities, it may be advisable to attempt their removal by means of flexile collodion or plaster-muslin, containing from 2 to 10 per cent. of salicylic acid.

JAMES GALLOWAY.

MOLLUSCUM FIBROSUM.—The name is applied loosely to certain forms of fibroma arising from the connective tissue of the skin and subcutaneous tissue. They usually make their appearance in early life, but become larger, and apparently more numerous, later on. They are often of congenital origin, due to defective development of the mesoblastic elements of the skin. In the majority of cases only a few small tumours may be noted; perhaps it may be said that there are few persons who do not develop small examples of molluscum fibrosum at some period.

The tumours are, however, frequently numerous. On palpating the skin small roundish gaps may be felt in the cutis due to the development of the peculiar fibrous tissue of the tumour. The tumours as they develop produce hemispherical projections from the surface, which may attain large dimensions; and these often become pedunculated as their size and weight drag on their attachment. They are in some cases innumerable; cases are not infrequent when, owing to their great numbers and size, they completely disfigure the parts affected; and when the whole body is affected, as is occasionally the case, the sufferer almost loses human semblance. These cases are usually accompanied by other anomalies, such as angiomas, pigmentation, and excess of hair; and not infrequently the sufferers are mentally deficient. Occasionally large areas of the skin are affected by overgrowths of similar character, giving rise to pendulous folds of skin, instead of isolated tumours. To such cases of the disease terms such as *molluscum pendulum*, *dermatolysis*, and *pachydermatocle* have been applied.

After reaching a certain size the tumours usually remain passive for an indefinite period, though occasionally some of them may shrink and disappear. They do not develop the characteristics of malignancy.

The tumours consist of bands of interlacing fibrous tissue bundles of differing consistence, but usually more or less oedematous. In many cases, especially when the tumours are numerous, there can be little doubt that they develop from the connective tissues of the peripheral nerves (von Recklinghausen), and are in reality *neurofibromata*. Such cases are often associated with multiple fibromata of the nerve-trunks.

TREATMENT.—No method of treatment has been suggested to prevent the development of the tumours. When they are in situations likely to be injured, or when they interfere mechanically on account of their size, they may be removed by surgical methods.

JAMES GALLOWAY.

MONOMANIA.—SYNON.: FR. *Monomanie*; Ger. *Wahnsinn*.—This term is falling into disuse by reason of its vagueness, and because it has been employed by various writers to denote different kinds of insanity. Some have used it to denote an insanity which is indicated by some one particular delusion, the mind remaining clear on every other point. Others mean by it an insanity without delusion, an *affective* or *impulsive* insanity, the essence of which is the absence of delusion, and the so-called integrity of the intellectual portion of the mind. Esquirol thought it a disorder of the faculties limited to a few subjects, with excitement, and gay and expansive passion; while, according to others, melancholia without delusion would be an instance of affective monomania. We may take it,

however, that all authors are agreed in using the term 'monomania' to indicate a partial insanity, which enables the patient to converse and act rationally to a considerable degree, and therefore renders his responsibility a matter of question. Such cases form the grounds of forensic contention, whether criminal or civil; but it is better to affix to them some more precise term, and to indicate symptomatologically and pathologically the exact nature of the mental and bodily condition of the alleged lunatic. See *INSANITY*, Delusional, p. 763.

G. F. BLANDFORD.

MONSTROSITIES AND MALFORMATIONS.

—Under the heading of 'Diseases of the Fœtus' (p. 549) the results of the action of morbid agencies upon the unborn infant during the foetal period of antenatal life have been dealt with. When, however, the causes of disease act upon the unborn in the embryonic or formative period of intra-uterine existence there is reason to believe that they produce monstrosities and malformations, and not maladies. Embryonic physiology is embryology, and embryonic pathology is disordered embryology or teratology; when the chief function of the organism is to form organs, the most striking result of disordered function will be malformed organs; normal embryogenesis and organogenesis become under pathological influences teratogenesis and morbid organogenesis. If this theory of the causation of monstrosities and malformations be accepted, much that is inexplicable otherwise is done away with. Of course the period during which malformations can originate is thus narrowed down to the earliest weeks of antenatal life; at the same time all anomalies of formation do not take origin in these few weeks, for some organs and some parts of the body are longer in passing through the embryonic stage than others; and so long as they are in the embryonic or formative stage they are liable under the action of pathological agencies to teratogenesis or malformation. There is thus a difference in degree only between the monstrosities and the malformations, and the usual mode of action of the teratogenic cause is to arrest embryogenesis or organogenesis, leaving as a permanent condition what should normally be only a passing or transitory one. Inasmuch, however, as in the formation of the human embryo various scaffoldings are used, reminiscent of the embryogenesis of organisms lower down in the zoological scale than man, the results of this arresting process become very complicated, as is seen, for instance, in the persistence of various portions of the branchial arches and clefts. One at least of the means by which these arrested developments are produced is defective growth of the amnion, on account of which the membrane either remains in close contact with the developing part exercising pressure upon it, or forms attachments to the embryo which afterwards make traction upon special regions and deform them. In this way a great many of the anomalies which used to be ascribed to foetal diseases can be much more satisfactorily explained; it is not a foetal disease setting up a monstrosity, but a monstrosity arising primarily; in a word, the monstrosities and malformations are the only diseases which can be expected to affect the embryo; they are the diseases of the embryo. The double monsters, however, and monstrosities by excess (showing redundancy of parts) can hardly

be explained by the theory of arrested development due to amniotic pressure, &c. For their origin it is necessary to consider the period of antenatal life preceding the embryonic—the germinal, in other words; there is much evidence to help to prove that the double character of the embryo is determined before the first embryonic rudiments appear in the embryonic area of the blastodermic vesicle. Possibly polyspermia or the entrance into and functional influence of more than one spermatozoon upon the ovum may be one at least of the ways in which double monsters or united twins are determined. When the malformation or monstrosity has been produced *in utero*, the monstrous foetus may be carried through the rest of antenatal life, for as a rule the placenta is not involved to a lethal extent; and it is remarkable to note to what an enormous degree the foetus may be deformed and intra-uterine life still be possible of continuance. It is this fact that has led some to conclude that the monstrosities found on the foetus at birth have been produced during the foetal period of antenatal existence.

CLASSIFICATION.—No scheme of classification yet proposed is altogether satisfactory, for malformations and monstrosities do not lend themselves to arrangement in linear series, but exhibit intermediate types or connecting links for which it is difficult to find a place, or which seem to be equally well placed in two, or even three, different groups. It will be sufficient for practical purposes to make two large divisions, in one of which are placed the malformations and monstrosities characterised by defect of formation or by altered relation of parts (monosomatous terata), while in the other are those with excess of formation as their prominent feature (polysomatous terata). The latter group will be considered first.

Polysomatous Terata or Double (and Triple) Monsters.—Under this heading come the cases of two (or very rarely three) foetuses united to each other with all the possible degrees of fusion, from those with a single body, four limbs, and a head, showing more or less duplicity, to those in which the foetuses are separate save as regards the vessels of the umbilical cords which anastomose with each other. The former are instances of what are commonly called double monsters or united twins, and the latter are known as allantoideo-angiopagous twins.

United Twins.—These may be of two kinds—symmetrical, in which it can be seen that two foetuses of fairly equal size are joined usually by corresponding parts, according to Saint-Hilaire's '*loi d'affinité du soi pour soi*;' and asymmetrical, in which one foetus is much smaller than the other, and is commonly described as parasitic upon it. As examples of the first group may be mentioned the thoracopagous twins, such as the Siamese brothers, in which there are two almost complete bodies united more or less extensively in the thoracic and abdominal region; the dicephalic terata, in which the lower part of the monstrosity is single while the upper part shows more or less complete duplicity (example, Rita-Cristina); and the syncephalic terata, in which the upper part of the bodies is so fused as to appear as single, while there are four lower limbs and sometimes also two vertebral columns in the lower part. Almost all the possible intermediate types have been recorded, and the leading types have thus been proved to

overlap and shade off into one another. As instances of the second group or parasitic monstrosities reference may be made to the cases in which a more or less defective foetus is attached to the thorax, or face, or sacral region of an otherwise normal twin; the name autosite is given to the latter, and parasite to the former.

Placental Parasites or Allantoideo-Angiopagous Twins.—Closely related to the rudimentary twin attached to the umbilicus of the autosite (gastro-parasitus) is the rudiment-twin attached to the umbilical cord or placenta of its normal brother or sister twin. These placental parasites are often the subjects of the most advanced degrees of monstrosity; they may be headless (acephalic), heartless (acardiac), trunkless (acornic), and even formless or rather globular (anidean or myelacephalic). That they continue to live *in utero* is due to their obtaining nourishment from the co-twin, for their vascular system is in communication (through the placental vessels) with its heart and circulation. They do not survive birth. Sometimes the placental parasite may be one of triplets, or, very rarely, of quadruplets.

Monosomatous Terata or Single Monsters.—Far more commonly met with than the double monsters are the cases of deformity or malformation in an infant which shows no sign of duplicity, and gives no indication that it has arisen from two embryos. Various modes of arrangement of anomalies in formation have been proposed; but for convenience we shall here group them under the various regions of the body. At the same time it is a common occurrence to find a foetus deformed in several parts, and in more than one region of the body, as, for example, in the cases of adhesions of the amnion to the foetus, where amputations of the fingers and toes, hare-lip, facial fissure, exomphalos, and spina bifida may all co-exist.

Cranial Malformations.—Perhaps the most common of the marked monstrosities of the cranium is anencephaly (sometimes but incorrectly termed acephaly). In it there is more or less complete absence of the bones of the cranial vault, along with a condition of open spinal canal. On the basis crani, which generally is directed backwards instead of upwards, a mass of fibrous tissue and blood clot is usually found, the brain being absent. The face of the foetus looks upwards, and there is no indication of a cervical groove anteriorly. The pregnancy which results in the birth of such a foetus is often complicated with hydramnios, and ends either prematurely or (less commonly) postmaturely. The malformation is compatible with intra-uterine, but not with extra-uterine existence. Iniencephaly is a state in which the cranium, which is present but defective in the occipital region, is sharply retroflexed upon the spine (retroflexion of the foetus), which is often partly open; in this way the head and trunk of the foetus form together a rounded mass with the limbs as appendages, and the cervical part of the spine may lie almost at the centre of this mass; in very advanced degrees of iniencephaly the gluteal muscles may be attached to the occiput. Microcephaly or unnatural smallness of the head is commonly associated with idiocy. Hydrocephaly, which is more probably to be reckoned as a malformation than as a disease, produces great enlargement of the head, but as the brain-substance is not increased but diminished by the presence of the fluid in the enlarged ventricles,

the individual may likewise be an idiot. When hydrocephaly is marked at birth it may cause some delay in labour; in cases of spina bifida there may be some degree of hydrocephalus without any external indication of it. Various swellings may be met with on the head of the foetus,—defects in the cranial bones allowing the escape of part of the contents account for some of these; according to their contents they may be encephalocoeles, hydran- cephalocoeles, or meningoceles; and according to their position they may be occipital, frontal, or parietal. If sepsis be avoided these swellings can sometimes be successfully removed, but there is always the risk of the subsequent development of hydrocephalus. Imperfect ossification of the parietal bone in the region of the obelion may predispose to the occurrence of subpericranial cephal-hæmatoma.

Facial Malformations.—The number of malformations which may affect the face and the organs of special sense is very great. One of the most striking of these is cyclopia or the fusion (more or less complete) of the two orbits and the two eyeballs into one central cavity and contents. Above this (rarely below it) is a projection or proboscis which indicates the nose; there may be also absence of the lower jaw (hypo-agnathia). Agnathia may occur apart from cyclopia, and may be associated with absence of the mouth or with microstoma; it is a striking fact that agnathia is rare in man but comparatively common in fetal lambs. Macrostoma or a wide buccal opening is often due to or combined with facial fissure (single or double) of the transverse type; evidently the anomaly is due to the persistence of the inter-maxillary fissure of embryonic life. Another type of facial fissure is the ascending or vertical one which passes up from the mouth at the side of the nose towards the inner angle of the orbit, and may be associated with malformations of the eye or eyelids. Hare-lip is a common malformation, and apt to run in families; bilateral fistula of the lower lip is much less common, and may be associated with hare-lip. The nose may show a mesial fissure, and congenital deviations of the septum are not rare; perforation of the septum also may occur as an antenatal anomaly. Anophthalmos is not often met with, but cryptophthalmos is more common; and there are many other anomalies of the eye, such as coloboma of the iris, aniridia, and corectopia. The external ear may be deformed in various ways: there may be a fissure in the lobe or a fistula in the upper part of the helix; and in front of it or attached to it may be found little fibro-chondromata or pre-auricular appendages supposed to be relics of the branchial arches; in agnathia the two ears may be approximated under the face, and give rise to otocephaly. Supernumerary tympanic ossicles have been recorded.

Cervical Malformations.—The commonest malformations in the region of the neck are of the nature of cysts or fistulae connected with permanent rudiments of the branchial arches and thyreo-glossal duct. The cervical auricles are generally of the nature of chondromata. Sometimes cervical cysts attain large and deforming dimensions, hygromata of the neck. There may be an accessory thyroid, or absence of the thyroid, or persistence of the thyreo-glossal duct.

Thoracic Malformations.—The thoracic walls may be defective at various points. When there is

a fissure or defect of the sternum the heart may project outside the thorax (ectopia cordis), and this does not necessarily lead to death. Cervical ribs may be met with, as also a congenital displacement upwards of the scapula. The pectoral muscles may be absent, an anomaly which is not uncommonly combined with absence of the nipple on the same side and with malformations of the hand and fingers, as if some common cause had interfered with the development of the chest and arm. Supernumerary mammary glands may be found in the axilla or below the normal ones (polymastia). The œsophagus may be imperforate or communicate with the trachea. Cardiac malformations, however, constitute the most important of the thoracic anomalies. They may be of the nature of imperfect closure of the interventricular or interauricular septa, of absence of obliteration of the ductus arteriosus, of stenosis or (rarely) obliteration of the pulmonary artery or (less commonly) of the aorta, or of transposition of the great vessels. See HEART, MALFORMATIONS OF.

Abdominal Malformations.—Among the structural anomalies of the abdomen and its contents are the various forms and degrees of defect of the walls, leading to exomphalos when the defect is widespread, and to umbilical hernia when it is small. Exomphalos is often associated with retroflexion of the spine, and the peritoneum may be continuous with the amnion, no true umbilical cord being present. Malposition of various parts of the intestine is not uncommon, and there may be atresia at various points; in the latter case the infant after birth will pass clay-coloured stools instead of the dark green meconium. The rectum may be absent or the anus imperforate; in the latter instance operative means will usually prove sufficient, in the former success is more doubtful. The lower end of the bowel may open into the bladder (atresia ani vesicalis), or into the vagina in the female (atresia ani vaginalis or vulvar anus). The bladder may be open to the front, ectopia vesicæ, and give rise to urinary incontinence, a condition which it has been found very difficult to correct; among the latest suggestions for treatment is transplantation of the trigone of the bladder into the colon. The two kidneys may be fused into one (horse-shoe), and displaced downwards into the pelvic brim; either of the ureters may be double; and there may be persistence of the urachus leading to abscess or cyst in the anterior abdominal wall. Umbilical fistulae may be caused in the same way or may arise from the opening at the navel of an omphalo-mesenteric duct. Supernumerary spleens occur.

Genital Malformations.—So important are the genital malformations that in some text-books a special subdivision is set apart for them under the name of Hermaphrodites, and it is true that many of them give rise to doubts as to the sex of the individual who is thus malformed. This remark applies specially to such malformations of the external genitals as hypospadias (an imperforate condition of the penis, the urethra opening on the under surface of it or in the perineum) or epispadias (urethra opening on the upper surface of the penis) in the male, and to imperforate vagina and vulva in the female, especially when combined with hypertrophy of the clitoris; but these cases are better termed pseudo-hermaphroditism, for the individual is not really anatomically or physiologically

of double sex, but is only of doubtful sex until the internal organs can be examined. Various forms of double uterus and vagina are met with which are due to the persistence of the original condition of duplicity of these organs. The testicles may be undescended or lying in the inguinal canal; in both of these circumstances it is doubtful if they are of any use.

Spinal Malformations.—An open condition of the spinal canal, or spina bifida, is a not uncommon malformation; it generally affects the posterior part of the spine in the lumbar or dorsal region, but it is also met with in the cervical region, and rarely in the anterior or lateral part of the spine. Through the opening the spinal membranes or the cord itself may project, giving rise to a tumour which often ulcerates after birth; but there may be no projection (*spina bifida occulta*), a condition sometimes associated with localised hypertrichosis and club feet. Other spinal malformations are congenital scoliosis and absence of vertebral bodies; and sometimes there are supernumerary coccygeal vertebrae giving rise to a 'tail.'

Malformations of the Limbs.—Many of the minor malformations of the limbs, such as club-foot and hand, webbing of the fingers, &c., are referred to elsewhere. *Symphodia* is a rare monstrosity in which the lower limbs are more or less completely fused into one, constituting the so-called siren foetus; not only are the limbs fused, they are also rotated so that the popliteal spaces face anteriorly; the external genitals are usually quite absent, and the lower end of the bowel grossly malformed. The limbs may show various degrees of imperfect development; they may be completely absent (*amelia*), or shorter than normal (*phocomely*), or defective in any of the segments (*ectromely*). Supernumerary digits are not uncommon (*polydactyly*), the extra digit being most often a little finger or toe; on the other hand, absence of one or more digits is met with (*ectrodactyly*). Any of the long bones of the extremities may be wanting.

Transposition of the Viscera.—*Situs inversus*, or *Heterotaxy*, is an interesting anomaly in which we find on opening the body-cavities that the organs all have the appearance that they would present if seen in a mirror. The stomach lies on the right side and the liver on the left, the spleen is on the right, and so on down even to the smallest differences, such as the height of the kidneys and the arrangement of the vessels. It is sometimes but not invariably associated with left-handedness. A condition, which at first sight resembles it, is due to congenital diaphragmatic hernia; for in it the intrusion of some of the abdominal contents into the thorax causes a displacement of the heart to the right side (*dextrocardia*); but the two conditions are quite different in their origin, although it is interesting to know that they have been met with associated.

Teratogenesis or experimental teratology is a product of recent years; it has been chiefly carried out with the hen's egg in incubation; and it has been found that by disturbing the normal incubation-conditions (by increasing the temperature or by injecting into the albumen poisons, microbes, and toxins) various forms of monstrous development can be produced, although it has not yet been made possible to foretell what type of monstrosity will result in any given case.

J. W. BALLANTYNE.

MONSUMMANA, Cave of, in Upper Italy.—Natural vapour-baths. See MINERAL WATERS.

MONT DORE, in France.—Simple thermal water, containing arsenic and soda. See MINERAL WATERS.

MONTE-CATINI, in Tuscany.—Thermal muriated saline waters.

MONTMIRAIL, in France (Vaucluse).—Sulphated saline, bitter waters.

MONTPELLIER, in the South of France. Variable, fairly warm, winter climate. High winds from N.E. and N.W. See CLIMATE, Treatment of Disease by.

MORAL INSANITY.—See INSANITY.

MORBID (*morbus*, a disease).—This word merely signifies *diseased*, and is used, in its several applications, as a technical or scientific term, in contradistinction to the term *healthy*.

MORBIDITY (*morbus*, a disease).—This term is employed to denote the amount of illness existing in a given community; and, as 'mortality' expresses the death-rate, so 'morbidity' indicates the sick-rate, whether the diseases be fatal or not.

Since health is an extremely ill-defined state, marked out by no absolute boundaries, and since many people suffer from diseases that are concealed intentionally or through ignorance, it becomes a matter of considerable difficulty to express with certainty the amount of illness that may exist at any time. Some information may, however, be obtained from the records of sick clubs and benefit societies, on which statistics may be based of the average time their subscribers are ill during the year, in relation to employment, age, locality, and other circumstances. From the statistics of these friendly societies it has been estimated that nine days in the year per member are lost through sickness.

By an investigation of this subject the rates of mortality come to possess an extended significance, for they thus indicate not merely the proportion between the living and the dead, but between the latter and the two classes of the living, namely, the healthy and the diseased; and, as a branch of State Medicine, they must doubtless come to take a prominent place. As further knowledge provides accurate facts and figures, the subject will have a distinct practical bearing, in estimating the value of men for work, if the average liability to disease and the total amount of illness an individual may expect to suffer be known; while it is reasonable to believe that as the 'aptitudes to disease' are further conditioned, the means for prevention may be extended.

W. H. ALLCHIN.

MORBIFIC (*morbus*, disease; and *facio*, I make).—This word is properly applied to any cause that produces a disease. Such a cause is often spoken of as a *morbific agent*.

MORBILLI (dim. of *morbus*, a disease).—A synonym for measles. See MEASLES.

MORBUS.—This is the Latin word for *disease*. Formerly it was frequently employed, but is not

much in vogue at the present day. It still persists in such terms as *morbus cordis*, disease of the heart; *morbus coxae*, disease of the hip-joint; *morbus cerealis*, ergotism; *morbus Brightii*, Bright's disease; *morbus cæruleus*, blue disease, congenital heart-disease.

MOROCCO, in North Africa.—A warm, healthy winter climate. Tangiers is exposed to cold, damp S.W. winds in autumn and spring, and to E. winds. Living is superior to Malaga. See CLIMATE, Treatment of Disease by.

MORPHINISM.—**SYNON.:** The Morphine-Habit; Fr. *Morphinisme*; Gr. *Morphiumsucht*. See HABITS.

MORPHŒA.—See SCLERODERMIA.

MORTALITY.—**SYNON.:** Rate of Mortality; Death-rate; Fr. *Mortalité*; Ger. *Sterblichkeit*.

DEFINITION.—The proportion of persons dying to those surviving under given circumstances; or, more usually, the proportion borne by the persons who die to the whole number of those subjected to the given circumstances.

Thus we may have to do with the annual mortality of the population of a country, a district, or a city; or of a body of men similarly circumstanced, as of clergymen or of lead-miners; or of bodies of men otherwise alike, but subjected to different conditions of climate, &c., as the British army; or of the population, or any section of the population, at special ages, as of infants in factory towns.

Or we may be concerned with the proportions of deaths to survivors, or to the whole number of entrants, during and after exposure to a special cause or causes of death, operating either speedily or during a protracted period. Hereunder come, for example, the mortality sustained by the population of Rio Janeiro, or New Orleans, during an epidemic of yellow fever; or that suffered by a number of persons in passing through an attack of enteric fever or pneumonia.

ESTIMATION OF MORTALITY.—The annual mortality of a population is reckoned, not on the numbers in existence at the beginning of a year, but on the average number in existence on the several days of the year, or, what is nearly the same thing, on the mean population of the year. The necessity of this becomes evident, when we consider that in our own country the large towns are mostly increasing at a very rapid rate, while many agricultural parishes and unprosperous places actually decline in population. In the towns, therefore, the death-rate, if reckoned on the last census, or even on the number believed or estimated to exist at the beginning of the given year, would come out higher than it ought to be, while in declining parishes it would be somewhat too low. Similarly the annual mortality of bodies of troops is calculated on the mean strength.

Two formulæ are in use for specifying death-rates. In the first the proportion of deaths is taken as unity: thus, the mortality in England and Wales in 1899 would be stated as 1 in 54. In the second, which is more convenient and is now generally employed, the number of lives at risk is taken as 100 or 1,000: thus the mortality of 1899 would come out 18·3. Either formula is convertible into the other by simple division: thus, $1,000 \div 46 = 21\cdot7$: and $1,000 \div 21\cdot7 = 46$.

The death-rates of large civilised countries in which registration is strictly carried out give a pretty fair representation of the viability of the population. So much may be said for England, Wales, and Scotland, and for most of the European states, but not, unfortunately, for Ireland, where the weakness of the registration laws makes the record defective.

MORTALITY OF NATIONS.—The following were the death-rates per 1,000 of most of the principal states of Europe during the period indicated—1884 to 1893 inclusive:—

Norway, 16·9	France, 22·4
Sweden, 16·9	Portugal, 24·0
Ireland, 18·1	Prussia, 24·1
Denmark, 18·9	Russian Poland, 24·4
England and Wales, 19·2	Germany, 24·6
Scotland, 19·2	Württemberg, 25·2
Switzerland, 20·5	Italy, 26·0
Belgium, 20·5	Servia, 27·0
Holland, 20·6	Saxony, 27·3
Finland, 20·8	Bavaria, 27·6
Japan (?), 21·0	Roumania, 30·0
Greece, 21·7	Spain, 31·0
Bulgaria (?), 22·1	Hungary, 32·2
	Russia (Eur.), 34·7

In Russia, Spain, Bavaria, Austria, Hungary, Italy, Prussia, Saxony, Servia, the high figures are largely due to the high mortality under five years of age; while Sweden, Denmark, Switzerland, Ireland, and Greece owe their favourable position largely to their small mortality under that age. And in all of them, except Russia, Austria, Hungary, Spain, and perhaps Greece, the greatest quinquennial mortality after childhood falls from 70 to 75 (in Norway over 75), so that the force of viability does not differ so much as the rate of mortality. In many of the British colonies it is lower than even in Norway. Thus the average mortality during the five years 1882–6 was in

Victoria, 14·8	New South Wales, 15·6
Queensland, 19·7	South Australia, 14·3
West Australia, 18·6	Tasmania, 15·6
New Zealand, 10·8	

and in 1895, which, however, was a very healthy year, the mortality rate was in

New Zealand, 9·91	New South Wales, 11·87
South Australia, 11·20	Victoria, 13·25
Queensland, 11·38	West Australia, 17·32
Tasmania, 11·38	

MORTALITY OF CITIES.—The mortality of cities is in this country almost invariably higher than that of the rural districts. But this rule does not apply to all other countries; the exceptions occur mostly where endemic fevers are prevalent in the country. Thus the mortality-rate in 1887 was in London, 19·6, in Edinburgh, 19·8, and in Dublin, 30·6; and in 28 other large towns in England it varied between 16·9 in Brighton and 28·7 in Manchester; while in 50 towns of the second class the extremes were 12·4 at Maidstone and 13·3 at Burton; 23·8 at Stockport and 24·9 at Wigan; the average of the 28 towns being 20·8 per 1,000, and of the 50 towns 19·0. In the same year the rural districts and small towns of England yielded an average rate of 17·4 only. There are a considerable number of districts, almost all rural, which year after year fall below 17; and 17 was accordingly fixed upon by William Farr as a kind of standard to be aimed at by sanitarians. And there are districts in England, and entire small counties in Scotland, where the corrected rate frequently falls below even 15 or 14.

The following table exhibits the death-rates experienced in 1878, and again in 1887, in a number of foreign and colonial cities :—

	1878	1887		1878	1887
Calcutta	37.7	24.0	Paris	24.0	23.0
Madras	48.8	40.0	Brussels	28.0	21.0
Bombay	41.8	26.0	Amsterdam	24.4	22.0
New York	24.8	26.0	Rotterdam	27.3	21.0
Brooklyn	20.1	23.0	The Hague	26.4	20.0
Philadelphia	18.0	22.0	Copenhagen	22.0	24.0
Montreal	30.9	—	Stockholm	22.4	21.0
Alexandria	45.4	38.0	Christiania	18.5	23.0
Melbourne	—	—	St. Petersburg	47.1	28.0
1873 and 1875	22.8	21.0	Berlin	29.9	22.0
Rome	29.8	29.0	Hamburg	26.9	27.0
Naples	33.1	—	Dresden	24.7	22.0
Turin	31.1	26.0	Munich	34.6	30.0
Venice	28.7	25.0	Breslau	29.9	29.0
Trieste	36.2	29.0	Vienna	29.6	26.0
Geneva	23.6	21.0	Budapest	40.3	32.0

The next table, including several of the same, with some additional cities, shows in several instances, though not in all, the effect of perseverance in sanitary improvement :—

	1882-91	1892-3		1882-91	1892-3
London	20.37	20.79	Vienna	21.53	24.09
Paris	23.80	21.97	Budapest	30.90	27.00
Brussels	24.39	21.63	Rome	31.16	29.02

ANALYSIS OF RESULTS.—These tables awaken, by the enormous differences between the several cities and countries, a curiosity respecting the causes of such differences, which, however, the figures themselves go far towards satisfying. It is at once evident that, whatever may be the case in the open country, cities suffer to a considerable extent in the ratio of their ignorance and neglect of sanitary laws, and of the poverty and squalor or barbarism of their populations. Mark, for example, the contrast between Philadelphia or Geneva, and Alexandria, Budapest, or St. Petersburg! Cities having a steadily warm climate, or a climate of extremes, are more unhealthy than those which enjoy a temperate one. By this consideration, combined with that of their superior civilisation, may be explained the favourable position of the cities of Western as compared with those of Eastern Europe. The short, hot summers are very fatal in the latter region, and even in Southern Germany and at Stockholm; while in Western Europe generally, and especially in Scotland, winter and spring are the deadly seasons. It is noteworthy that in most of the large cities of Italy the short, sharp, and changeable winter is not less deadly than the hot summer and malarious autumn.

In Great Britain the influence of climate *per se* on the annual mortality of the several cities and districts is not very great; and its effects are obscured by those of other agencies. But if we confine our attention to the rural districts, where the disturbing factors are less important, we shall find that the rates of mortality are on the whole slightly more favourable in the north than in the south. Of all the counties in Great Britain Orkney- and-Shetland stands best, with an annual crude mortality, on an average of 10 years, of 15.13, which would be still lower if standardised; and Shetland, the more northern division, stands better than Orkney. Great Britain is, therefore, no exception to the rule that in Europe mortality decreases from south to north. This is in no way inconsistent with the fact that throughout Great Britain winter

is the deadly season, and cold is more fatal than heat, thoracic than abdominal diseases.

INFLUENCE OF SEASONS.—The following were the death-rates of the four seasons in England and Wales, in 1868-77 :—

	Winter	Spring	Summer	Autumn	Year
In the chief towns	25.8	22.5	23.1	24.2	23.7
In the small towns and rural districts	21.7	19.3	17.2	18.5	19.0

In Scotland the seasonal mortality, owing, doubtless, to the less intensity of the summer heat, follows pretty nearly the order of the English small towns and rural districts. Thus, in 1878: winter, 25.2; spring, 23.2; summer, 19.8; autumn, 20.4; year, 22.3. In Ireland (1881-90) the proportions were: winter, 21.7; spring, 19.1; summer, 14.7; autumn, 16.4. Here the influence of cold is strongly marked.

It would seem, however, that in London, in the early part of the seventeenth century, when the death-rate, owing to the closeness and filthiness of the city, was fearfully high, the maximum was attained in summer, the figures standing as follows in 1606-10, during which years the plague was absent. Average mortality per cent.: winter (J. F. M.), 1.4; spring, 1.5; summer, 2.7; autumn, 2.0; total, 7.0.

INFLUENCE OF DENSITY OF POPULATION.—In accordance with a principle already laid down, that in communities sufficiently advanced to furnish mortality statistics the death-rate diminishes with the progress of civilisation, the mortality of London has since the seventeenth century gradually and greatly diminished. At the beginning of the nineteenth century it had sunk to 29, in 1840-49 it was 25.3, in 1870-78, 23, in 1881-90, 20.31, and in 1891-99 only 19.6.

The death-rate is also diminishing in France, Belgium, the Netherlands, Sweden, Germany, and Italy, in all of which countries the population is believed to be advancing in comfort and general well-being; but in those parts of southern and eastern Europe, where comparatively little advance has taken place in these respects, no such diminution can be demonstrated.

Nor, though evident in London and in several other great towns, can a large and permanent diminution of the death-rate be positively affirmed of Great Britain generally. In Scotland, indeed, there was a decided increase from 1855 until 1876, when a decline, which may prove transient only, set in. And in England no improvement could be shown for many years before 1871, after which date there was a long and almost unbroken succession of years of low mortality concurring with a generally low temperature and excessive fall of rain.

The great antagonistic influence in Great Britain may be found in Dr. Farr's principle, 'That mortality increases with density of population.' And 'urbanisation' advances so rapidly in Great Britain, that all the efforts and devices of sanitary and medical science are scarcely able to do more than neutralise its evil effects. The apparent improvement is largely due to the diminution of phthisis and of typhoid fever. Contrary to the general belief, the expectation of life in males aged over 20, and in females over 45, was actually less in the period

1870-80 than in that of 1838-54, and less over 45 in both males and females in 1880-90 than in 1870-1880. But the expectation at birth has been very greatly increased owing to the diminished mortality in childhood and youth.

SOURCES OF FALLACY.—It may be as well to advert to some of the principal sources of fallacy, which hamper us in appreciating national and local death-rates. One of these is the varying number of births. The birth-rate ranges in the Continental States of Europe from about 40 in Germany and Austria, and even more in Russia and Hungary, down to 25 in France; and in Britain from 48 or 50 in some coal and iron districts, down to 22 in the county of Sutherland, and 14·8 in what is called the *City of London*. The late Dr. Letheby maintained that a high birth-rate was a direct cause of a high death-rate, owing to the great mortality among infants. This was an error; the two often concur, but the former is not a cause of the latter, unless where the infants perish in enormous proportion, as in most parts of Russia and in Spain. Thus in seven fertile provinces of Central Russia the birth-rate is 5·27 per cent., and the death-rate 4·09, about half the children perishing in infancy. But the usual result in England of a large and especially of an increasing birth-rate, is to augment in the community the proportion of children beyond infancy, and of young persons, who ordinarily suffer a very low death-rate as compared with old or even middle-aged persons. The favourable rates prevailing among these young persons overpowering the unfavourable ones of the infants, and of the comparatively small number of old people, the apparent death-rate is actually diminished, instead of being increased as Letheby supposed. And this points to the true reason why the death-rate of France is higher than that of England, whereas the expectation of life in the two countries is about the same at most ages, the birth-rate of France being so extremely low (Bertillon). *The lower the average age of the population, the lower the death-rate.*

A considerable amount of emigration or immigration affects the death-rate in proportion to the average age of the migrants. Thus the mortality of most great and growing towns would stand far worse than it does, were it not for the large numbers of young and healthy persons from the country who settle in them. Watering-places and residential towns appear somewhat healthier than they really are, by reason of the numbers of young domestic servants who form a large portion of their population. Various modes have been proposed for exhibiting fairly the true or standardised death-rate of communities, instead of the 'crude' one; or for adjusting the mortalities for differences of age- and sex-constitution of population. It is in our colonies that the effect of migration on the death-rate can best be studied. The unexampled death-rate of New Zealand, already quoted, is the result of two kinds of causes, one set of which we may call real, the other factitious or apparent. The former are the cool, equable climate, and the orderly and comfortable condition of the population; the latter are the constant stream of mostly youthful immigrants, and the very high birth-rate, now beginning to slacken.

INFLUENCE OF AGE AND SEX.—The influence of age and sex on the mortality in England and Wales may be best shown in a tabular form.

Mortality per 1,000 at twelve groups of ages in males and females in the 41 years 1838-78:—

	All Ages	0-	5-	10-	15-	20-	25-
Males	23'3	71	8	4	6	8	9
Females	21'2	62	8	4	7	8	9
		35-	45-	55-	65-	75-	85-
Males	23'3	13	18	32	67	147	311
Females	21'2	12	15	28	59	134	287

The superiority of the women is here well-marked, except during childhood and the years of early married life and much child-bearing. And this difference has been still greater during the later decades, owing chiefly to the decreasing vitality of males after the prime of life; thus in 1871-80 the death-rate of males from 45 to 55 was 20, that of females only 15.

Mortality per 1,000 at eleven groups of ages in males and females in the decade 1881-90:—

	All Ages	0-	5-	10-	15-	20-	25-
Males	20'2	61	5	3	4	5	7
Females	18	52	5	3	4	5	7
		35-	45-	55-	65-	75-	—
Males	20'2	12	19	34	70	162	—
Females	18	10	15	28	60	147	—

INFLUENCE OF RACE.—The influence of race is usually difficult to separate from that of habits of life. In Europe the Jews offer the most notable example. It may be sufficient to quote from Oesterlen Neufville's statistics of Frankfort-on-the-Maine, which show that there the average age of Christians at death was 36·9 years, but that of Jews was 48·7; and from Hoffman, the death-rate of the Jews of Prussia, which was only 21·6 per 1,000, against 29·6 among the Christians.

INFLUENCE OF STATION AND OCCUPATION.—The influence of station and occupation on mortality is very great. The subject has been carefully handled by Dr. Farr in the Supplement to the Registrar-General for England's thirty-fifth *Report*, and again by Dr. W. Ogle, in the Supplement to the forty-fifth, and by Dr. Tatham in that to the fifty-fifth. Briefly, it may be said that of all trades or professions that can be isolated, clergymen, barristers, farmers, agricultural labourers, gardeners, gamekeepers, and grocers seem to stand best in this respect. Booksellers, paper-makers, shipwrights, wheelwrights, and carpenters also suffer but a small mortality; so do lace- and hosiery-makers. Schoolmasters and teachers go on well up to fifty-five. Fishermen stand well. Solicitors, domestic servants, watchmakers, shoemakers, saddlers, bricklayers, and blacksmiths range not far from the average rates; so do bakers (though such is not the current opinion), and most kinds of weavers and of shopkeepers. The workers in iron, as a rule, experience but a low mortality in early life, but a rather high one as they grow older; the same may be said of millers, and, somewhat strangely, and no doubt for very different reasons, of Roman Catholic priests. Artists come out pretty well, musicians very badly.

Tailors begin very ill, and end fairly. Medical men, alas ! perish frequently in early life, and only attain a respectable position after fifty-five; the figures for chemists, also, are rather high. The figures for drapers, formerly bad, have improved of late years, as have those for commercial travellers and clerks. Those for miners, naturally enough, are not very different from those for iron-workers, except the tin and copper miners of Cornwall, who stand badly. Tobacconists, as might be expected, suffer heavily until middle life. Printers, bookbinders, coal-heavers, carriers, hairdressers, hatters, messengers, bargemen, and workers in lead (painters, &c.), glass-manufacturers, dock labourers, porters, railway employés, butchers, cabmen, draymen, and chimney-sweepers, all suffer a very high mortality. And about the worst positions are occupied by dealers in alcohol (brewers, innkeepers, and especially hotel servants), and by costermongers, potters, cutlers, and filemakers. The chief causes of a high death-rate in males are evidently alcohol and the irritation of inhaled dust; and, in a less degree, foul air in early life, and too violent exertion later on.

These facts are of considerable practical interest in relation to questions of life-assurance.

MORTALITY OF DISEASES.—Some acquaintance with the mortality of diseases, and the extent to which it is influenced by age, sex, climate, season, &c., is also of great value for prognosis. Information on this subject will be found under the heads of the several diseases; moreover, the limits of this article are not sufficient to admit of much discussion of the subject.

A few facts respecting the acute infectious diseases will, however, be of interest.

1. *Typhoid Fever.*—The average death-rate of enteric fever was put by Murchison, in accordance with British, French, and German hospital statistics, at 17·4 per cent. There is a good deal of ground for putting the average mortality of children and youths at 11 or 12, but it is probable that only the worst cases occurring in children find their way into hospitals. Over fifty years of age somewhere near one-half usually die (Liebermeister). The mortality from typhoid fever would appear, however, to be decreasing at a more rapid rate than the number of cases of the disease.

Still, the mortality in epidemics occurring among soldiers on campaign is often enormous. In the Nile campaign of 1898 it was 28 per cent. on admissions, in the Soudan in 1884–5 39 per cent. Even in the British army in India, for the last ten years, it has averaged 26·17 per cent., while in soldiers at home it has been as much as 19·16. In the Bloemfontein epidemic it is believed to have been about 21. It would seem that young adults have no advantage over other subjects in this respect. Some epidemics are less deadly than others. In that of Maidstone the percentage of deaths was 7·6. There is a mass of evidence showing that where the cold-bath treatment is carefully applied the mortality is reduced to a singularly constant average of between 7 and 8. See p. 136.

2. *Measles.*—The mortality from epidemics of this disease is often as low as 2 or 3 per cent., but it has been known to rise to 30 per cent. under unfavourable circumstances, as where children, or even adults, are crowded together in a hospital. It seems to be very deadly in Belgium. Among 'virgin' communities (as in well-known epidemics in Iceland,

Faroe, Madagascar, Fiji) the mortality is sometimes frightfully large. It is comparatively small in summer; and decidedly small among the comfortable classes, owing doubtless to the exercise of greater care. It is beyond comparison greatest in the second year of life, and by the tenth has become quite trifling; but adults *may* die of measles.

3. *Scarlatina.*—There is a prodigious difference in the deadliness of different epidemics of this disease, even in the same locality. In Southern Europe it is comparatively a mild disease; in Britain, Sweden, Austria, it is most severe; yet even here eighty successive cases may occur without a death. But a mortality under 10 per cent. may be considered moderate (Thomas, in Ziemssen); it is often much higher. It is at its maximum from the second to the fourth year, but continues very deadly up to ten or twelve; by fifteen it has almost reached a minimum, but, unlike measles, continues to be somewhat formidable throughout life, especially to parturient women. Season and station in life make little difference in its deadliness.

4. *Diphtheria.*—The severity varies extremely in different epidemics. It is much more deadly in Germany and Austria than in Great Britain.

5. *Small-pox.*—Small-pox did and does, in unvaccinated communities, where it has long been at home, destroy somewhere about 10 per cent. of the population; and of persons unprotected by vaccination who are attacked, 40 per cent. often perish. Among 'virgin' communities it is still more deadly. Age makes comparatively little difference in its fatality.

6. *Whooping-Cough.*—The death-rate of this disease is very large in the first year of life, declining afterwards like that of measles, but rather more rapidly, and becoming quite insignificant before the tenth year. Whooping-cough is more fatal in winter than in summer, in towns than in the country, among the poor than among the rich; but these differences, except the first, are not very well-marked. See VITAL STATISTICS.

JOHN BEDDOE.

MORTIFICATION (*mors*, death; and *facio*, I make).—A popular name for gangrene. See GANGRENE.

MORTON'S DISEASE.—A term applied to a form of metatarsal neuralgia in which attacks of severe pain occur at the base, generally of the fourth, but occasionally of the second toe. Ill-fitting boots and prolonged standing are among the accredited causes of the condition. In many cases carefully made boots and other appliances afford relief; in others excision of the head of the metatarsal bone may be necessary.

MORVAN'S DISEASE.—An affection met with especially in a district of Brittany, and named after the physician who first described it. The disease has strong points of resemblance to anæsthetic leprosy. It is a chronic affection, implicating the upper extremities more especially, and characterised by neuralgic pains, cutaneous anæsthesia, and painless and destructive whitlows. Well-marked neuritis and perineuritis have been found in the bodies of those dying of the disease; and in some cases these changes have been associated with syringomyelia. See SPINAL CORD, Special Diseases of: Syringomyelia.

MOUNTAIN SICKNESS.—SYNON. : Fr. *Mal des Montagnes* ; Ger. *Bergkrankheit*.

DEFINITION.—This term has been applied to a group of symptoms comprising lassitude, dyspnoea, headache, and palpitation, which affect some people climbing mountains of considerable height. The lower limit of altitude at which this affection appears cannot be defined, but most sufferers begin to experience discomfort at about 16,000 feet, which usually increases as the climber rises higher. The term 'mountain sickness' is unfortunate, as nausea and vomiting, though they sometimes accompany the attack, do not appear to be essential symptoms, but rather depend upon coincident dyspepsia from indigestible food.

ETIOLOGY AND ANATOMY.—The physical and physiological causes producing this condition are most complex, and it is difficult to assign their relative values. The following have been put forward by various observers : Deficiency of oxygen in rarefied air ; deficiency of carbonic acid, associated with partial paralysis of the vagus ; diminution in the amount of hemoglobin with lessened capacity for absorbing oxygen ; cerebral and spinal anæmia, resembling that occurring in caisson-disease ; asphyxia associated with cerebral congestion. See CAISSON-DISEASE.

Exhaustion from bad food, from want of training, food, and sleep, or from cold or excessive heat, tend to bring on the malady or increase its severity. Stagnation of the air in a mountain hollow has the same effect, whereas the rapidly moving air on a ridge or summit relieves the distress. Prolonged residence at a high altitude (10,000 to 12,000 feet) does not seem to protect the individual when he reaches a greater height. Personal idiosyncrasy is undoubtedly a factor.

SYMPTOMS.—The following are the symptoms, the more common ones being placed first : Lassitude, weakness and dragging of the legs ; increased and irregular respiration-rate, inability to 'hold the breath' for more than a few seconds ; headache, giddiness, palpitation (the pulse often rising to 120 per minute and becoming irregular), lividity of the face and hands ; loss of appetite, nausea, and occasionally vomiting ; mental hebetude, sleepiness, and even unconsciousness.

DIAGNOSIS.—The effects of ptomaine-poisoning (especially from tinned foods), exhaustion from the heat of the sun or from fatigue, are the conditions most likely to be confused with mountain sickness.

PROGNOSIS.—There is little danger to life provided the sufferer can, if necessary, descend to a lower level. Even if unable to do this, the symptoms will often pass off with rest and suitable food, though liable to return if another attempt be made to ascend.

TREATMENT.—This consists in rest, with the head low, maintenance of the body-warmth, the administration of stimulating and easily digestible food or meat extracts, and, if necessary, descent to a lower level. The use of oxygen carried in steel cylinders has been suggested as a means both of relieving mountain sickness and enabling climbers to reach greater heights when so affected, but the question of portability is obviously a serious one.

W. A. WILLS.

MOUTH, Diseases of.—The principal diseases of the mouth may be thus enumerated : (1) Inflammation and its results, including (1a) Thrush ;

(2) Gumboil ; (3) Ranula ; (4) Lingual Dermoids ; (5) Salivary Calculus ; (6) Salivary Fistula ; and (7) New-growths and Epulis. Diseases of the tongue and the teeth are treated of in other articles.

I. Stomatitis.—SYNON. : Fr. *Stomatite* ; Ger. *Mundschleimhautentzündung*.

DEFINITION.—Inflammation of the mouth.

VARIETIES.—Inflammation of the mouth may be *acute* or *chronic*. According to the more striking lesions found, we speak of *catarrhal*, *follicular*, *ulcerative*, and *gangrenous* stomatitis. Again, inflammations of the buccal mucosa may be classed according to their cause, for example, *syphilitic*, *scorbutic*, or *mercurial* stomatitis.

ÆTIOLOGY.—The principal causes, predisposing or exciting, of stomatitis are : Mechanical irritants such as a sharp tooth or a tooth-plate ; the eruption of teeth ; chemical irritants, especially alcohol ; burns and scalds ; hot tobacco-smoke ; mercurialism ; digestive disturbances ; the growth of parasites in the mucosa, such as those of thrush, cancrum oris, erysipelas, diphtheria ; syphilis and scurvy.

SYMPTOMS.—In *acute catarrhal* forms the mouth is hot ; and the mucosa is more or less red, swollen, tender, and unduly sensitive to heat, salt, spices, and the like. All these changes are least marked upon the dense hard palate and gums. The secretion of mucus is increased, and it may form a tough slimy layer upon the surface, more or less turbid from contained epithelial cells and leucocytes. The excessive redness and raw appearance of the surface are largely due to the rapid shedding of the surface-epithelium ; but in less intense cases, white patches of all shapes and sizes indicate increased production of epithelium, the cells remaining adherent for some time. In the less intense forms, especially when of some duration, the mucous glands on the lips, cheeks, and palate swell and form reddish-grey nodules or even small cysts, often surrounded by a ring of injection. This is the form known as *follicular* stomatitis. Sometimes the follicles break down and form small ulcers. But there are certain forms of stomatitis, of which more or less extensive ulceration is characteristic. One of these is especially known as *ulcerative stomatitis*.

Ulcerative stomatitis (putrid sore mouth) is not a further development of the above-described acute catarrh. It occurs chiefly in sickly children living under faulty hygienic conditions. After a slight febrile illness or malaise for two or three days, the child is noticed to eat with some difficulty, to suffer from more or less salivation, and to have a very foul breath. The cheek is perhaps swollen. On one side of the mouth, sometimes on both, one or more grey-based ulcers will be found upon the cheek, gums, and tongue. These may extend in depth till the alveolus is bare, there being no line between ulcerative stomatitis and cancrum oris (see CANCRUM ORIS). If left alone, these ulcers generally heal in seven to fourteen days, but they may become chronic. Ulcers are very prone to form in stomatitis resulting from mercurialism, scurvy, or syphilis.

In *chronic catarrh* of the mouth the chief signs are undue sensitiveness of the mucosa, and the presence of white patches (leucoplakia). Smooth red patches may also occur. Fissures may form in these patches. This chronic epithelial overgrowth derives its chief importance from the fact that it is sometimes the forerunner of epithelioma. The chief causes of chronic catarrh appear to be smoking,

dram-drinking, indulgence in hot spices, and syphilis; but frequently no cause is evident.

TREATMENT.—The avoidance of irritation, and the treatment of any general disease or digestive trouble, which may be regarded as a cause of the stomatitis, are the first points to be attended to. Food should be taken cool, with little or no salt, sugar, or hot spice; alcohol and smoking should be forbidden. The feeding of infants at the breast and, still more, of bottle-fed children, should be inquired into, and all defects remedied. The mouth should be wiped out after each meal with a rag moistened with some mild antiseptic. Borax-lotion or a little powdered borax, allowed to melt slowly in the mouth, is very soothing. In acute cases ice is grateful.

In *ulcerative stomatitis*, chlorate of potassium should be given internally with due care, and used also as a gargle. It is almost a specific. Borax-lotions are useful; and it is well to begin the treatment by wiping the ulcer and thoroughly applying pure phenol, cocaine or chloroform being used. Finely powdered iodoform should be dusted on the sore once daily. The hygiene of the mouth and of the whole body should be cared for. Change of air is most valuable. Nitric acid or ammonia and bark form an excellent tonic; and cod-liver oil and iron are generally useful later.

In *chronic leucoplakia*, treatment in syphilitic cases should include painting the patches with a lotion of bichloride of mercury (gr. ij–v ad 3j). In simple cases they should be painted with bicarbonate of potassium (gr. xx ad 3j), or chromic acid (gr. v–x ad 3j), the latter solution to be used every second day.

1a. Thrush.—**SYNON.**: Fr. *Muguet*; Ger. *Soor*; *Schwämmchen*.

Thrush is a parasitic stomatitis which occurs chiefly in young infants, and usually in such as are depressed in health, congenital syphilis thus ranking as a predisposing cause. It is not, however, rare to find infants in good health attacked. Adults do not, as a rule, suffer from this parasite, except towards the end of exhausting illnesses, especially phthisis; so the appearance of thrush in adults is usually of evil omen. Rarely a non-parasitic stomatitis or sore-throat depresses the mouth-tissues of adults sufficiently to allow the parasite to grow.

The thrush parasite is the *Oidium albicans*. Grawitz's statement that this is identical with the *Mycoderma vini*, or mould of wine, is generally received as correct. It affects mucosæ covered with stratified epithelium, especially that of the mouth and fauces; it is not uncommon in the pharynx and œsophagus, but is rarely found growing lower in the alimentary tract. It is sometimes found in broncho-pneumonic foci, having been inhaled. The parasite grows in the middle layers of stratified epithelial laminae, and consists of numerous mycelial threads mixed up with spores and fine granular debris. The neighbouring epithelial cells are destroyed and ultimately thrown off, leaving what looks like an ulcer; but almost always the deepest layer of epithelium remains covering the papillæ.

SYMPTOMS.—It is said that the first sign of thrush is some general heat and redness of the mouth, together with the secretion of a sticky layer of mucus of acid reaction, containing many cells, among which spores and threads are already recognisable. Then small white roundish patches form, and run together into larger ones. The patches are sur-

rounded by a vascular ring. At first they are pretty firmly adherent, later on easily detachable, leaving 'ulcers.' Sucking may become painful. More or less disturbance of the gastro-intestinal functions is usually present. Mothers suckling children with thrush are very liable to sore nipples.

If the above be taken as the typical symptoms of thrush, we must add that in many cases the parasite excites no inflammatory phenomena whatever, suggesting a parallel with tinea tonsurans, which also may or may not cause inflammation.

Thrush is commonly said by mothers 'to go through' children. This means that, while thrush is present in the mouth, and the child is perhaps suffering from gastro-intestinal symptoms, redness, excoriation, and perhaps ulceration appear at the anus, and spread more or less widely to adjacent parts. Some think that in the child's depressed condition of health any tendency to intertrigo or eczema would show itself, and that acrid evacuations would render the anal region specially liable; but in the writer's opinion the above history is very strongly in favour of congenital syphilis, and he finds that treatment generally supports this view.

TREATMENT.—Care in feeding children regularly at proper intervals, in the selection of milk and preparation of food for hand-fed children, scrupulous cleanliness with regard to bottles, spoons, &c., used in feeding the child, and especially the precaution of wiping out the child's mouth thoroughly after each meal with rag or wool wet with glycerine of borax, make up a highly successful prophylaxis against thrush. When the trouble is present, all these precautions must be carefully observed, and a food suitable to the patient must be found. Gastro-intestinal symptoms must be relieved. The patches of thrush in the mouth and throat should be frequently painted with the Glycerinum Acidi Borici, the B.P. solution of sulphurous acid (1 in 6 of water), salicylic-acid solution (1 in 250), sulphate-of-sodium solution (3j ad 3j), or almost any other non-irritant antiseptic. Good hygienic surroundings, change of air, and supporting treatment are often necessary to bring about the recovery of feeble patients, and are helpful to all.

2. Gumboil.—**SYNON.**: *Parulis*; Fr. *Parulie*; Ger. *Zahnfleischgeschwür*.

DESCRIPTION.—A 'gumboil' is a small abscess pointing upon the gum. The term 'alveolar abscess' includes all gumboils and many other cases; for, while indicating that such abscesses almost invariably start in the alveolus or socket of a tooth, it says nothing as to their pointing, the directions in which they tend being very various.

The cause of an alveolar abscess is almost invariably caries of the tooth in connection with which the abscess arises. The irritant is therefore most probably some septic organism which gains entrance to the pulp-cavity and excites an inflammation of the pulp, which spreads along a fang. Usually the whole tooth dies as a result. An abscess may form at the base of a tooth already dead, though not carious, the irritant probably entering between the socket and the tooth, but not necessarily, for an abscess is rarely found connected with a sound living tooth, and the pulp of a sound, though dead, tooth may be found putrid. An abscess occasionally arises in connection with a partially erupted tooth, especially a wisdom-tooth in the eruption of which there is difficulty; or, again, a cyst round a retained

tooth may suppurate and resemble an ordinary alveolar abscess.

In the ordinary alveolar abscess pus is formed about the apex of the fang within the alveolus, whence the acute early pain. The bone around the apex of the fang is rapidly softened; and the outer plate of the jaw, being decidedly thinner than the inner, yields, and the pus escapes into the tissues outside the jaw. More or less swelling of the face now occurs, and, coincidentally, diminution of pain. The pus then forces its way towards the surface in the direction of least resistance, and very often bursts on the gum, or between this and the cheek. But this is by no means always the result, the point of bursting being sometimes so distant from the seat of irritation that the latter runs some risk of remaining unrecognised. The following, more or less unusual, points are therefore noted. Abscesses from the upper incisors, especially lateral, not uncommonly burrow between the hard palate and its coverings, and open far back; rarely they burst into the nose, causing a discharge from the nostrils; and still more rarely through the lip. The palatine roots of the upper molars may also cause a palatine abscess; while pus starting from the external fangs is sometimes conducted, apparently along the buccinator fascia, to the cheek, where it bursts. Affection of, and suppuration in, the antrum is most likely to result from the first upper molar fangs; but caries of any upper tooth, especially molar or bicuspid, may be the cause of continued suppuration. Abscess from the lower incisors rarely bursts on or below the chin. Abscess from the lower molars and bicusps, more commonly than from any other teeth, bursts upon the face, just above the lower edge of the mandible. From the lower wisdom-tooth an abscess may burst far back upon the fauces, near a molar or bicuspid, or below the jaw. In a few cases the pus of these latter abscesses has burrowed, from insufficient drainage, down the neck, even as low as the clavicle. Rarely an abscess from a lower molar finds its way through the inner plate of the jaw.

SYMPTOMS.—At first the tooth appears long (from periostitis), and is the seat of pain, which is relieved by pressure upon the tooth. Soon it becomes so tender that all pressure is unendurable, and pain increases rapidly, often becoming very severe. After twenty-four to forty-eight hours the pain diminishes or disappears, and the face swells more or less. Finally the abscess, if left to itself, bursts. It may discharge freely through the opening, and sometimes through and around the tooth. Sometimes it undoubtedly heals, and the tooth remains, firmly fixed; or a sinus remains, giving little trouble if it open into the mouth, much disfigurement if on the face; or frequent abscesses may form. Abscess from a non-erupted or carious wisdom-tooth is specially likely to be accompanied by chronic trismus. Grave results, such as death from pyæmia, are very rare.

TREATMENT.—An acute alveolar inflammation may be aborted by disinfecting the tooth-cavity with pure carbolic acid, scarifying the gum, and applying frequent hot fomentations to the mouth. Where the above treatment fails to relieve the early acute pain (toothache), pus not having yet made its escape from the alveolus, extraction of the tooth (discovered by smart tapping with a steel instrument if the patient cannot clearly indicate which is aching) is the best remedy. When the tooth is

valuable, Tomes has suggested that an incision should be made down to the bone opposite the diseased tooth, and the outer plate of the jaw drilled at the level of the apex of the fang—not a very painful operation, he says. When abscess is present and the tooth of little or no value, removal of the tooth often provides sufficient drainage; but if the patient cannot be easily watched, an incision also should be made into the abscess between the cheek and jaw, especially as, with cocaine, it adds little to the pain. This incision should always be made immediately when the abscess is threatening to burst through the skin; also when pus is stripping up the soft parts from the hard palate. The skin over the pus may then be painted with flexile collodion, and elastic pressure maintained with a bandage over cotton-wool. Thinned red skin may thus often be preserved. When bursting through the skin seems inevitable, it should always be anticipated by a short incision, through which a fine tube may be introduced. The result of this will be a much in-drawn scar, but in the course of months the depression diminishes till it may become hardly noticeable. In making incisions between the jaw and cheek, the points to be attended to are to use a small scalpel, cut close and parallel to the jaw, and direct the point a little towards the bone. The presence of pain and swelling are reasons for the immediate performance of extraction, and not for its postponement till these symptoms shall have subsided. In all chronic sinuses of doubtful nature about the mouth, lower part of the face, or neck—even as low as the clavicle—the teeth should be carefully examined and put in order. It will probably be useless to endeavour to save a tooth which has given rise to chronic sinus or to recurrent abscesses. Even after removal of the tooth and gouging of the alveolus, the sinus may remain for months, but ultimately close. An opening upon the face may in these cases close if a probe be passed along the sinus and freely cut upon from within the mouth. To preserve a tooth, the pulp-cavity is to be emptied and rendered aseptic, and then it and its prolongations must be filled. If the process is successful, the tooth heals in as does a clean foreign body; if it fail, fresh abscesses form and extraction becomes necessary. See **TEETH**, Diseases of.

3. **Ranula.**—**SYNON.**: Fr. *Grenouillette*; Ger. *Ranula*; *Fröscheingeschwulst*.

DESCRIPTION.—Ranula is a cystic swelling situated more or less upon one side of the frænum linguæ, rarely upon both sides; affecting both sexes at all ages, but chiefly occurring in adult life. It is not uncommonly referred to an injury after which it has appeared; it increases slowly, rarely becomes larger than a chestnut, is painless, and causes inconvenience only by its size. The swelling in the mouth is smooth, rounded, tense or soft, elastic or fluctuating, and has a bluish pellucid appearance strongly suggestive of its cystic nature. The mucosa is non-adherent and free from folds over the swelling, across which tortuous veins often wind. Only with ranulæ of exceptional size is any swelling perceptible below the jaw.

PATHOLOGY.—This is doubtful, and several modes of origin have been described. Distension of Wharton's duct may certainly occur, but in the majority of cases this duct is clear, and a probe introduced passes over the swelling. Wound of the duct and extravasation of saliva may cause the

appearance of a cystic swelling. Some believe that the sublingual gland and its principal duct (Bartholin's) are the chief seats of ranula, but this is unlikely. Fleischmann's bursa—on each side of the frænum, between the mucosa and the muscles—is probably sometimes the seat of a pathological effusion. Dilatation of a mucous gland may occur beneath the tongue, especially that known as the Blandin-Nühn gland from the names of its describers. This was found adherent to the cyst by von Recklinghausen and Sonnenberg in one instance, and they adduced many good reasons for thinking that this gland was, at least, a very common seat of the cystic distension known as ranula.

TREATMENT.—A thick silk seton may be tied and remain in for three to seven days, according to the degree of irritation excited; this may be serious, and run on to abscess. Other methods of treatment are (a) opening the cyst freely, drying it out, applying pure carbolic acid, and packing with iodoform gauze; (b) cutting a V-shaped flap in the wall, and fixing its apex into the cavity with a stitch; (c) dissecting out the whole cyst, or the superficial part of it, upon which the Blandin-Nühn gland would lie (von Recklinghausen). Woakes reports a cure from the injection of a saturated watery solution of chromic acid.

4. **Lingual Dermoids.**—**DESCRIPTION.**—Lingual dermoids occur in two situations—in the mid-line between the genioglossi, and on either side of the tongue, between the genioglossus and mylohyoid. They are rare, and are due to the inclusion of an epithelial germ connected either with the invagination of the mouth-pit or stomodæum, the closure of the first visceral arch or of the first branchial cleft, or with the foetal thyro-glossal duct (His), which extends from the foramen cæcum of the tongue to the thyroid isthmus, and is regarded as the remains of the hypopharyngeal diverticulum or protrusion from the foregut to form the thyroid isthmus. Cysts between the genioglossi and in the mid-line of the neck, as low as the thyroid isthmus, are probably connected with the thyro-glossal duct, or with the union in the mid-line of the upper branchial arches; cysts on either side of the mid-line with closure of the branchial clefts or with the junction of the stomodæum and foregut. The contents vary, being sometimes the usual cheesy, epithelial mass, with or without pale hairs intermixed; sometimes only a brownish mucoid fluid, in which float small masses of fatty epithelium. The lining of the cyst is generally a delicate layer of stratified cells which vary somewhat in function, as the contents show.

Though really congenital in origin, and usually reaching a size to attract notice in early life, these cysts often remain small for many years, and then, without obvious cause, begin to enlarge. They may not appear until mid-life or even later. They form smooth, round or oval, tense, elastic and fluctuating, or doughy swellings beneath the tongue, in the mid-line or on one side; they are usually firmer to the touch than ranulæ; unlike ranulæ they project chiefly towards the skin and but slightly into the mouth, the mucosa over them being normal unless some dilated veins ramify in it; they never have the translucent appearance of ranulæ, but it is said that some have a yellowish appearance owing to the colour of the sebaceous matter showing through. They cause inconvenience in proportion to their size.

TREATMENT.—This consists of complete removal by dissection, when inconvenience or unsightliness renders treatment desirable. All central and most lateral cysts should be removed by incision below the jaw; the cyst, when bared, is but loosely attached to its surroundings, and it may, if necessary, be emptied. The cavity left should be obliterated by purse-string stitches, and the skin wound closed.

5. **Salivary Calculus.**—**SYNON.** : Fr. *Calcul Salivaire*; Ger. *Speichelstein*.

DESCRIPTION.—Friable concretions, composed chiefly of phosphate of lime, are not very uncommon in the ducts of the parotid, submaxillary, and sublingual glands. They vary in size from a pin's head to a filbert, or even larger, are elongated in form, and not infrequently they form around some small foreign body—a seed or a bit of woody fibre—which has made its way into the duct. They may lie in the substance of the gland, but are usually found in the duct. They are easily felt from the mouth, but are rarely complained of unless they give rise to the following symptoms. Without obvious cause inflammation causes complete or partial obstruction of the duct; the gland swells and becomes hard, but is neither tender nor painful as a rule. In the case of the submaxillary duct, the side of the tongue and floor of the mouth are red, and more or less swollen; an abscess may form in the latter situation. *See* CONCRETIONS.

TREATMENT.—If a concretion can be felt, either with a finger or with a probe passed along the duct, an incision should be made on to it, and the calculus removed with care, lest it break and the fragments excite more inflammation than did the entire mass. Local inflammation requires a poultice outside, and constant fomentation of the mouth with hot solution of boric acid or borax; if an abscess form it should be opened and treated similarly.

6. **Salivary Fistula.**—**SYNON.** : Fr. *Fistule Salivaire*; Ger. *Speichelfistel*.

DESCRIPTION.—Occasionally the duct of the parotid gland (Stensen's duct) is wounded or involved in an ulceration, or an abscess forms in its track and bursts externally. In such cases a salivary fistula is likely to be the result. The secretion from the parotid instead of making its way into the mouth dribbles over the cheek.

TREATMENT.—Whenever the parotid duct is involved in a wound of the cheek, an opening opposite the wound should be made into the mouth; the duct should be most carefully sutured, as also should be the tissues superficial to the duct. When a fistula has formed, all ulceration should have ceased for weeks or months before any operation is undertaken for its closure. Then the first point is to secure free drainage into the mouth for saliva by puncturing the mucosa of the cheek in two places from the depth of the fistula, and passing a stout bit of silver wire through the holes and tying it in the mouth as a ring. The closure of the opening in the skin has been effected by light cauterisations; by paring the edges, dissecting up skin-flaps for some distance and bringing them together; or, best of all, by removing the edges and adjacent skin and twisting in a flap to fill the gap. All movement of the cheek should be avoided.

7. **New-Growths.**—Most of these start from the tongue or jaws. Papillomata and epitheliomata are not uncommon on the inner surface of the cheek, palate, and floor of the mouth; they present their

usual characteristics, and are treated by removal. The swollen mucosa round a sinus, leading to a sequestrum of the hard palate, sometimes presents a striking resemblance to an epithelioma.

Epulis.—SYNON.: Fr. *Epulide*; Ger. *Epulis*.

DESCRIPTION.—‘*Epulis*’ is a somewhat loosely used word applied to tumours projecting upon the gum. Without an adjective indicating the nature of the growth, it really conveys nothing beyond the situation of the mass; but custom has practically limited its application to two common and often clinically indistinguishable pathological varieties, the fibrous and the myeloid.

These tumours spring from the fibrous tissues of the gum, or from the alveolar periosteum and bone—the myeloid grows always, and the fibrous usually, having a connection with bone. Sometimes small growths of the latter nature come away attached to the fang of an extracted tooth, as if they had originated from the fibrous covering of the fang.

Epulides are commoner in connection with the lower than with the upper jaw. They form smooth, rounded, or lobulated masses, usually quite sessile, varying from pinkish-white through red to purple-red in colour, and firm or semi-elastic to the touch. They are covered at first by the epithelium and mucosa of the gum, but ultimately they may ulcerate from pressure against the teeth or other irritation. Most commonly they present between two teeth, displacing one or more; or they may project upon either the superficial or the deep surface of the alveolus—the latter but rarely. Growth is not very rapid, and there are no signs of deep infiltration of the jaw.

TREATMENT.—This consists in free removal of the growth, together with any bone in connection with it. Sometimes this may be effected under cocaine, especially with growths on the superficial surface of the gum; in other cases an anæsthetic is necessary, two or three teeth must be extracted, and the whole thickness of the alveolus cut away with a small saw and bone-forceps. After such treatment, recurrence is unusual; but myeloid growths sometimes show exceptional malignancy, and require specially free handling.

STANLEY BOYD.

MOVABLE KIDNEY.—See KIDNEYS, Diseases of, p. 835.

MOVEMENT, Therapeutical Uses of.—SYNON.: Movement-Cure; Kinesitherapeutics; Fr. *Gymnastique Suédoise*; Ger. *Kinesitherapie*.

DESCRIPTION.—The movements employed are of three classes, namely: (1) *active movements*, executed by the patient himself, or by the patient aided by an assistant; (2) *passive movements*, performed by the assistant on the patient; and (3) *acts of resistance to movements*, whether executed by the assistant against the patient, or by the patient against the assistant.

USES.—The several classes of movements, for which mechanical arrangements are also contrived, when scientifically employed, are used in the treatment of paralysis, curvatures of the spine or limbs, and injuries and diseases of the joints. Movements of the nature of friction or shampooing are also employed in the treatment of certain diseases of internal organs. See FRICTION; MASSAGE; and SHAMPOOING.

MUCOID DEGENERATION.—A form of degeneration, which is associated with the production of a mucus-like substance. See DEGENERATION.

MUCOUS PATCH.—SYNON.: Mucous Tubercle; Condyloma; Fr. *Plaque Muqueuse*; Ger. *Breite Feigwarze*.

When the term ‘condyloma’ is used, ‘syphilitic’ ought always to be prefixed, to avoid confusion with the simple form of growth. See CONDYLOMA.

DEFINITION.—A patch of syphilitic papular eruption upon mucous membrane or moist skin.

ÆTIOLOGY.—Mucous patches belong to what are commonly known as the secondary manifestations of syphilis; they may appear early or late, both in the acquired and in the inherited disease, and are very liable to return time after time.

Experimental inoculation of the discharge of mucous patches has proved that it is capable of producing a hard sore at the point of insertion, followed by general symptoms; and clinical observation shows that these lesions are the most frequent means of spreading syphilis.

DESCRIPTION.—Mucous patches on the skin appear as flattened elevations of a round or oval shape, with a broad base, of a reddish colour, and generally covered by a thin grey pellicle. When in close proximity they coalesce, and form a mass of irregular shape and size, which may be fissured and ulcerated. When situated upon a mucous membrane they are usually less raised, and whitish in colour, especially in the throat, where they have been termed *plaques opalines*. The primary sore may assume the appearance of a mucous patch, especially in women. The growths also sometimes become warty on the surface.

Favourite seats of mucous patches are the genital organs, and the moist skin about the anus. They may also be found at the umbilicus, in the axillæ, auditory meatus, or nose, on the nipples, and between the toes; in stout and dirty persons they may be met with wherever folds of skin meet and perspiration collects. They are very common about the lips, mouth, tongue, and throat; and occasionally are seen on the cervix uteri. Want of cleanliness favours their development, as does irritation from any cause, especially smoking and chewing tobacco.

TREATMENT.—Mucous patches, being highly infectious, should always be got rid of as soon as possible. In the mouth or throat, pure carbolic acid, or a solution of chromic acid (twenty grains to the ounce), may be applied from time to time, and an astringent mouth-wash used several times a day. Mucous patches on external parts usually disappear quickly under strict cleanliness and the application of calomel (one part) and oxide of zinc (three parts), care being taken to keep opposed surfaces apart with lint or wool. If the growths persist, carbolic acid or nitrate of silver or the acid solution of nitrate of mercury should be applied. General treatment must of course be carried out at the same time. See SYPHILIS.

ARTHUR COOPER.

MUCOUS RALE.—An adventitious sound heard on auscultating the chest in certain forms of disease, and due to the passage of air through viscid fluid in the bronchi. See PHYSICAL EXAMINATION.

MUCOUS TUBERCLES.—See MUCOUS PATCH.

MULTILOCULAR (*multus*, many; and *loculus*, a small space).—A term applied to cysts and other

forms of growths, and to pulmonary cavities, when they consist of many small spaces or loculi. See CYSTS.

MULTIPLE NEURITIS.—A synonym for peripheral neuritis. See NEURITIS, MULTIPLE.

MUMPS.—SYNON. : Epidemic Parotitis; Cynanche Parotidea; Fr. *Oreillons*; Ger. *Mumps*.

DEFINITION.—An acute, febrile, infectious disease; attended by swelling of the salivary glands—especially of the parotids; and ending in resolution.

ÆTIOLOGY.—This is an affection more commonly seen in young persons—boys, growing girls, and young men; but it may occur in adults of either sex who are much with those affected with the disease, and who have not had the complaint before. Mumps rarely attacks the same person twice. It may occur as an epidemic in institutions, such as schools and barracks. It is usually conveyed directly from person to person, and is infectious even before the glands are affected, as well as for two or three weeks afterwards. It has an incubation-period of from fourteen days to three weeks.

ANATOMICAL CHARACTERS.—The disease is occasionally limited to one parotid gland, but generally spreads to submaxillary and sublingual on the same side, and not infrequently involves all six salivary glands as well as some of the cervical lymph-glands. It is probable that the inflammation starts from the duct. The surrounding tissues are swollen. Seldom does there appear to be any fibrinous exudation poured out; and still less frequently do the tissues suppurate, although the inflammation may spread to the middle or internal ear. The swelling completely disappears about three days after the fever. On the subsidence of the local lesion a so-called metastasis to the testicle and other glandular and fibrous structures may occur; atrophy of the affected testicles may follow. The sheaths of the nerves and the surfaces of the heart may be affected, especially in those cases in which orchitis has occurred.

SYMPTOMS AND DIAGNOSIS.—Some general symptoms always precede the local manifestations of mumps; they may be so slight as almost to escape notice; or fatigue by day, restlessness at night, slight fever, sore-throat, and vomiting may mark the prodromal stage. After these symptoms have persisted for a few hours or days the fever rises rapidly and the pain and swelling in the parotid or submaxillary glands begin.

One restless night follows, either from pain, or from fever, or both. Sometimes the pain is severe, and the temperature only elevated by one degree; sometimes the fever is more evident. It generally reaches 100° F. or 101°, and frequently rises to 103° or 104°; at this point it is not long maintained, but subsides as the local lesion is established, falling to the normal, or even below it, on the third or fourth day of the disease. The temperature may be low while the swelling is still marked and painful; and in some cases appetite returns before eating is easy. This happens when the patient is kept at rest in bed. Without such precaution, sudden and great elevations of temperature may occur at the end of the first week, either without serious local mischief, or with orchitis, deafness, tinnitus of one ear, and albuminuria, not always transient; rheumatism, and heart-

affections, leaving traces both of pericardial and of endocardial inflammation, may also occur.

From face-ache and enlarged lymphatic glands, the sudden sensation of pain or stiffness in the parotid or submaxillary gland, following on the general symptoms, and absence of any such local trouble as usually affects the lymphatics, together with the history of a possible infection, will generally suffice for the diagnosis of mumps. Further evidence is obtained on examining the spot, where, besides the deeply seated swelling, considerable tumefaction of the parts surrounding the gland exists near the lobe of the ear, filling in the hollow behind the jaw, soon increasing to such an extent as to involve more or less the whole of one side of the face, and passing down on to the neck. If the sublingual glands are affected the tongue is raised. Coincidentally with the appearance of this enlargement, the pyrexia declines in some cases; while in others some days elapse before the subsidence of the fever. Pain is now complained of, and the patient can no longer open his mouth to the usual extent. Yawning excites severe pain; in fact, it can hardly be effected. Mastication and speaking are greatly impaired, and the sufferer prefers to fast, and to remain silent, rather than endure the pain involved in the effort to perform either act. The saliva may be largely increased or much diminished in quantity. Pressure over the swelling is painful; and the sensation afforded by manipulation is that of an elastic tumour, with a slightly softer feeling in the centre. The skin over the swelling may be slightly reddened; often there is no deviation from the normal colour, the skin remaining pale, but glossy, and oedematous. In many cases these symptoms are not nearly so severe, and the disproportion between the amount of distortion of the countenance and the actual suffering is as astonishing to the patient as to the friends. Most frequently the affection is limited to one side of the face; but as the swelling of the one side subsides, the other may become involved, when it runs through the same series of events, with, possibly, an interval of a few days between them. Rarely are the two sides simultaneously affected; but in such a case the uneasiness, pain, and discomfort are of course greatly increased. After the continuance of these symptoms for about six or eight days, they begin to abate, the oedema lessens, the pain is lost, the stiffness and tension disappear, and in a few days the face acquires its usual appearance. A mild uncomplicated case endures about a fortnight. Occasionally there is left, for some time after this, a certain degree of hardness in the neighbourhood of the parotid, which gives no uneasiness, and can rarely be mistaken for tumour.

COMPLICATIONS.—In nearly a third of the cases in adult males orchitis occurs. The epididymis is occasionally involved. In females, ovaritis, vulvitis, or mastitis may be found, but they are rare. Cases are described in which the testicle was affected while the salivary glands escaped. Orchitis may precede, or accompany, but usually follows the swelling of the parotid, at an interval of not more than three weeks. Increase of fever and the usual local signs occur. Rarely is the orchitis bilateral. In the case of the girl the vulva becomes the seat of oedema, and on pressure over the region of the ovary pain is elicited. When the orchitis abates, the parotid may again take on the inflammatory condition. Meningitis is to be feared on sudden subsidence of the inflammation of the parotid, if

no orchitis follow the disappearance of the original affection. If the middle or internal ear has been involved permanent deafness may supervene on the affected side. Delirium, amblyopia, conjunctivitis, albuminuria, or gastro-intestinal disturbances are occasional complications.

PROGNOSIS.—This is almost invariably favourable in mumps, except in the very weakly and in the tuberculous, or in the rare event of meningitis being developed. It may be said to be always a disease of a comparatively trivial nature, producing considerable pain and much discomfort, but not endangering the life of the sufferer. In very exceptional instances the inflammation of the parotid terminates in abscess. The indications of such an untoward result are increased pain in the centre of the swelling, hardness, and dark red appearance of the skin over the spot. In time the abscess discharges outwardly, or into the external auditory meatus. Atrophy of the testis follows orchitis in 70 per cent. of the cases (Laveran).

TREATMENT.—A patient suffering from mumps should be confined to his bed during the febrile stage. But little treatment, beyond rest and care for the week or ten days the disease lasts, is required. The bowels may require relief, but all strong purgatives should be avoided. It may be well to give some simple saline, as bicarbonate of potassium with lemon juice, and diluents during the first few days; ice is always grateful. A dose of chloral hydrate may be required at night (in children a grain for each year of the patient's age) if there be any restlessness.

As to local treatment, not much is required, unless the pain be unusually severe. It will be sufficient in most cases to protect the part from the air by means of cotton-wool and a light handkerchief. Should more active interference be called for, some anodyne may be used, or soothing embrocation, such as the opium liniment, belladonna liniment, or external warmth. If there be the slightest tendency to suppuration, indicated by increase of fever and tenderness over the gland, with redness of the overlying skin, fomentations must be applied, and so soon as distinct fluctuation is discovered the abscess must be opened. The application of leeches is useless in reducing the inflammation, or in staying the formation of the abscess. They may be of service in lessening the pain of metastatic orchitis or ovaritis; but these are well treated by the same gentle means employed in the case of the parotid itself. Tepid sponging is of use during the course of the disease, and a warm bath may be required when metastasis threatens. Sometimes wine or brandy is required.

Considerable anæmia and much debility may persist even when mumps has been mild in its course, especially in the weakly or unhealthy, so that tonics, with iron and cod-liver oil, may have to be continued for some time. C. MUIRHEAD.

MÜNSTER AM STEIN, near Kreuznach, in Rhenish Prussia.—Muriated saline waters. See MINERAL WATERS.

MURMUR.—This term, as used in auscultation, was originally applied to the natural sounds heard over the lungs in respiration; but its employment has since been extended to include a great variety of auscultatory sounds connected with the heart, the blood-vessels, the placenta, &c. See PHYSICAL EXAMINATION.

MUSCÆ VOLITANTES (*musca*, a fly; *volitans*, floating about).—See EYE, AND ITS APPENDAGES, Diseases of.

MUSCLES, Diseases of.—SYNON.: Fr. *Maladies des Muscles*; Ger. *Muskelkrankheiten*.

1. **Acute Inflammation.**—SYNON.: Myositis.

(a) Inflammation of muscle, leading to exudation and suppuration, arises chiefly as a result of injury or rupture of a muscle. Sometimes, however, it appears to arise spontaneously, particularly in the tongue, diaphragm, and psoas muscle; in the last situation forming one variety of psoas abscess. In such cases it is probable that micro-organisms have been carried to the part by the blood or lymph. The symptoms are pain, tenderness and swelling, corresponding to the seat of the inflammation. Exudation of serum and of lymph takes place, and subsequently an abscess may form; occasionally the process goes on to gangrene.

(b) Secondary inflammations and formations of pus are of more frequent occurrence than simple inflammation and abscess. They arise in the course of the various forms of pyæmia and of the acute specific fevers, or may be due to extension of inflammation from neighbouring diseased bone. The presence of such secondary abscesses in muscles is especially characteristic of glanders and farcy, where inflammatory infiltrations of various sizes appear in many of the muscles, especially those of the arm. Disintegration takes place in their centre, and a collection of puriform fluid results.

(c) *Polymyositis* (Dermato-myositis).—This rare affection is characterised by swelling of the muscles in different parts of the body, with oedema of the subcutaneous tissues and an erythematous rash in the affected regions. The disease is probably toxic in nature, some cases having been definitely connected with the eating of shell-fish. The onset is gradual, with fever and feeling of weakness. Later there is acute pain in the muscles, generally those of the extremities first; later the muscles of respiration and deglutition may be involved. Death is frequent in severe cases. Microscopically, the affected muscles show hyaline degeneration with interstitial infiltration of leucocytes. The condition has to be distinguished from trichinosis, in which there are digestive disturbances and more affection of the face. The parasites must be sought for to render diagnosis certain (see p. 465). Treatment must be directed to the relief of pain and maintenance of the patient's strength. The use of hydragogue purgatives may aid in the elimination of the poison.

2. **Chronic Indurating Inflammation and Syphilitic Disease.**—In this form of inflammation there is proliferation of cells in the interstitial tissue, causing the muscle to become hard and painful. The whole muscle may be attacked, or the process may be limited to one or more portions. Infants are often attacked by chronic inflammation of the sterno-mastoid muscle. The whole muscle becomes hard and painful, but rarely suppurates. The disease usually yields to soothing external applications; but if it be of syphilitic origin, the use of internal antisiphilitic remedies may be required. In adults chronic indurative myositis of a syphilitic character may occur in the sterno-mastoid, the various muscles of the leg and arm, the temporal and masseter muscles, the tongue, and other parts. The disease may appear either as a diffuse

inflammation, with the usual signs of pain on movement, tenderness and some swelling—or sometimes a series of beaded swellings; or as a circumscribed inflammation, with an abundant infiltration of nucleated cells. If the inflammation does not soon subside, the cellular exudation becomes organised into contracting fibrous tissue, and the compressed muscular fibres atrophy. In diffuse myositis permanent contraction of the muscle may result from this cause; in circumscribed syphilitic myositis a fibrous tumour in the interior of the muscle may result; sometimes a gummy tumour is formed. Syphilitic tumours thus formed in the muscle bear a great resemblance to malignant tumours. Indeed, it is often found that the only means of distinguishing the two clinically is by the effect of iodide of potassium in causing the disappearance of the former.

3. **Myositis Ossificans.**—Ossification of muscle is a rare result of chronic inflammation or irritation. It is observed to occur in muscles which are subject to pressure, as the deltoid in soldiers, and the adductors of the thighs in riders. In the condition known as Myositis ossificans there takes place a slow, gradually advancing fibrosis of the voluntary muscles, followed in many places by the formation of some bone. The disease may begin in childhood, and its onset is sometimes attributed to injury. The muscles of the back, at first tender, gradually become stiff, so that no flexion is possible: the limbs sometimes become rigid. In course of many years the patient is reduced to a condition resembling a bronze statue, his whole body being rigid and immovable. The cause of the disease is unknown. It appears natural to regard it as a chronic inflammatory process with subsequent conversion of the fibrous tissue into bone. No treatment is known which will influence the course of the malady. The diaphragm, heart, and facial muscles usually escape.

4. **Rheumatic Inflammation.**—The morbid changes in this form of inflammation rarely pass beyond the stage of congestion and serous exudation, though occasionally proliferation of the interstitial tissue may occur, and callosities may be formed. See RHEUMATISM, MUSCULAR.

5. **Hæmorrhage.**—Hæmorrhage takes place in muscle not only from injury, but frequently in the course of typhus and typhoid fevers and pyæmia; also in leucocythæmia.

6. **Rupture.**—Violent contraction of a muscle, without external injury, may lead to partial rupture of its fibres—for example, the gastrocnemius. The violent spasms of tetanus occasionally cause complete rupture of a muscle, particularly of the muscles of the back, the rectus femoris, and the psoas. Rupture of muscles has been known to occur in the delirium of fever; and may be the cause of abscess forming in muscle, as described above.

TREATMENT.—The treatment of ruptured muscle consists mainly in rest; in the support of the muscle by uniform bandaging; and in suitable measures, should abscess form.

7. **Lesions of Sensibility.**—(a) *Myalgia.*—This term is given to a painful condition of the muscles arising in those who are in feeble health. The pain is similar to that which is present in a muscle after long-continued and fatiguing exertion—for example, in the limbs after a long walk, or in the diaphragm and intercostals after violent laughing. In persons who are debilitated, pain may

arise in the muscles after very slight exertion, and this constitutes myalgia. It is often accompanied by cramps at intervals. The pain is most commonly felt at the tendinous insertion of the muscle. The abdominal muscles are frequently the seat of myalgia, such as the costal origin of the external oblique—causing, according to some authorities, that pain in the side which is so common in women—and the pubic insertion of the recti. The muscles of the back, and especially the trapezius, also suffer; the muscles of the limbs much less frequently. When situated in the trunk, myalgia is often mistaken for some congestive or inflammatory condition of the liver, spleen, or other viscus lying beneath. The pains of myalgia are distinguished by their hot and burning character. They are increased by exercise of the affected muscle, and disappear when it is relaxed or artificially supported. However severe the pain may be, the pulse remains unaffected; but it is usually uniformly weak and fast.

The muscles or their fibrous connections are also the seat of pain in the condition known as muscular rheumatism.

TREATMENT.—The muscles should have rest and support by bandaging. Tonic treatment is required. Friction and counter-irritation do little good. Exercise is of no use, unless combined with fresh air and good diet.

(b) *Muscular anesthesia.*—See MUSCULAR SENSE, Disorders of.

8. **Spasm or Cramp.**—This painful affection is too well known to need description. It occurs chiefly in the muscles of the calf, often in persons who are quite healthy. It is most frequent after exertion, and may then be due to an auto-intoxication. Cramps are also a prominent feature in cholera and in certain forms of poisoning, especially by metallic irritants. Treatment in ordinary cases is by forcibly stretching the muscle and maintaining it thus for a few minutes. Kneading the muscle may aid in affording relief.

9. **Atrophy and Degenerations.**—(a) *Simple atrophy.*—Simple atrophy of the substance of muscular fibres arises either from general defective nutrition, during the course of wasting diseases, such as phthisis, in cachectic conditions, or after severe fevers; or as a local condition from disuse of the muscle. The muscles become pale and flabby. The ultimate fibres are reduced in volume, but preserve their anatomical characters, still showing the longitudinal and transverse striation. The atrophy is sometimes so advanced in parts that the muscular substance of the fibre entirely disappears, and nothing is left but the sheath of the sarcolemma, which appears in the form of fibrous bands between the remaining muscular fibres.

As a local condition, atrophy is most frequently seen in muscles in the neighbourhood of a diseased joint, or in a paralysed limb. In these cases the atrophy is usually combined with more or less interstitial deposit of fat between the ultimate fibres, constituting *fatty infiltration* of muscle. Occasionally the amount of fat is so great as to cause an actual increase in bulk of the muscle, so that it appears hypertrophied. The atrophic and other changes arising in paralysed muscles are considered in their appropriate articles. Fatty infiltration of muscles may also arise as a primary condition, when there is an excess of fat in the blood, and atrophy of the muscular substance results from it.

(b) *Fatty degeneration*.—Here the fat is deposited, not between the ultimate fibres, as in fatty infiltration of muscle, but in their interior. Rows of minute granules appear in the longitudinal striæ, and gradually increase until the whole breadth of the fibre is occupied by them, and nothing is left but the sarcolemma. When the degeneration reaches this extent, it is of course irrecoverable. Muscles affected by this change become very soft and friable. This degeneration is met with much oftener in the heart than in voluntary muscles. It is sometimes associated with atrophy of the fibres in the muscles of limbs attacked by certain forms of paralysis. It is met with also in fever and phosphorus-poisoning, granular degeneration being the first stage. *See FATTY DEGENERATION*.

(c) *Granular degeneration*.—Granular degeneration of muscles occurs in fevers and acute diseases. The fibres become swollen and opaque, being filled with fine granules. These clear up on the addition of acetic acid; this test distinguishing granular from fatty degeneration. The muscles which are affected by it are soft and friable and easily rupture. The fibres no doubt ultimately recover their natural appearances; but if the disease be severe and long-continued, granular degeneration advances to fatty degeneration, as is seen in cases of phosphorus-poisoning.

(d) *Waxy degeneration; Zenker's degeneration; Myositis typhosa*.—The affected fibres swell and lose their striation; and become of a homogeneous, translucent aspect. After a time transverse fractures appear in each fibre, dividing it into a series of short cylinders. The nuclei of the sarcolemma also multiply. The change does not attack all the muscular fibres of a part uniformly; for healthy and degenerated fibres are seen side by side. It is observed chiefly in typhoid fever, cholera, and other acute febrile diseases, being often associated with the granular degeneration. It is usually found in the adductor muscles of the thigh, the abdominal and pectoral muscles, and the diaphragm; appearing in patches of one or more square inches, pale and glassy; gradually becoming softened and pulpy. It is now considered to be a condition of *coagulative necrosis* of the muscle. It is frequently associated with hæmorrhage into the substance of the muscle.

(e) *Fibroid degeneration*.—Fibroid degeneration of muscle has already been referred to as a result of myositis. Chronic or repeated inflammation, of a rheumatic or syphilitic character, leads to the formation of fibrous tissue in muscle, and the muscle becomes of a tough, whitish character.

10. *Tumours*.—Muscle is subject to growths of a sarcomatous and cancerous nature, the latter being necessarily secondary to tumours elsewhere. Fatty, cartilaginous, vascular and other tumours are also met with in this tissue, but rarely. Myomata, or tumours consisting of muscular tissue, are also found. *See TUMOURS*.

11. *Parasitic Affections*.—The chief disease of muscles belonging to this group is that due to the presence of *trichine* (*see* ENTOZOA). The *Cysticercus cellulosus* is also sometimes found in muscles. *See also* MUSCULAR SENSE, Disorders of; and MYOPATHY.

MUSCULAR SENSE, Disorders of.—By the term 'Muscular Sense' is meant the sensory impressions by which we are aware of the state of the muscles during active or passive movements. The degree of muscular sensibility is estimated by the appreciation of the difference between weights held so as to cause but little difference in the stimulation of the cutaneous nerves; and also by the perception of posture, active or especially passive, so produced as to cause an equal stimulation of the cutaneous nerves in the different positions. It is probable that the knowledge is due to impressions from afferent nerves which arise in the connective tissue between the fibres, especially in the muscle-spindles. They seem to be normally stimulated, either by compression, as when the fibres are widened by contraction; or by tension, as when the muscles are elongated. It is only when such stimulation is great that the impressions so affect consciousness as to cause a true sensation, as in forcible extension of a muscle or very strong contraction. When very intense, or when the nerves are hypersensitive, actual pain is felt, as in a strong pinch, or cramp, or extension after cramp. Such pain may be produced through the same nerves, since we are familiar elsewhere with pain as the result of irritation of visceral nerves, whose normal impressions do not directly affect consciousness. The fibres apparently course with the motor fibres in the mixed nerves, but pass to the spinal cord in the posterior roots. The impulses thus generated seem to act first on the spinal cord, then on the cerebellum, and ultimately on the motor cortex of the brain.

HYPERÆSTHESIA.—Increase of the common sensibility of muscles is not unusual, e.g. after cramp; and the muscles become extremely tender in peripheral neuritis such as is caused by alcohol. The tenderness is shown both to pressure and extension. Very little is known of simple increase of the muscular sense except in the form of pain. The sensation of restlessness impelling movement has been attributed to muscular hyperæsthesia, but without sufficient reason.

ANÆSTHESIA.—Diminution of the muscular sensibility is occasionally observed, commonly in consequence of disease of the nerves, sometimes of the nerve-centres, and is usually associated with a diminution of other forms of sensibility. Loss of muscular sense, however, may be present when cutaneous sensibility is unimpaired. The affections with which muscular anæsthesia is commonly observed are locomotor ataxy, some central diseases, and hysteria. In tabes it is probably the cause of the ataxy; it bears no necessary relation to the change in cutaneous sensibility.

SYMPTOMS.—In muscular anæsthesia the patient is unaware of the degree of force exerted by the contracting muscles, and is dependent for his knowledge of the position of his limb, and of its movements, mainly upon cutaneous impressions, if these are preserved. Ignorance of the degree of contraction interferes with muscular co-ordination, by rendering this dependent on cutaneous and ocular perceptions. The condition of the muscular sense is ascertained by observing the accuracy of movement with and without closure of the eyes, by

determining the extent to which the patient is aware of the posture of the limbs in passive movements, and especially by ascertaining the sensitiveness to movement against resistance so applied as to affect the cutaneous nerves as little as possible. The best method for this purpose is to suspend a weight, in a bag or cloth, to the limb, and observe (a) the minimum which can be recognised; and (b) the least increase in a greater weight which can be distinctly perceived. The sensibility of the two limbs may be conveniently compared. In each of these points the muscular sense may present a deviation from the normal, and the change in the two is not always proportioned. The minimum recognisable, and the minimum difference recognisable, vary in different parts. The latter amounts in the case of the arm in health to a difference of $\frac{1}{10}$ th in a weight of three or four pounds. Balls of similar size and appearance, but of different weights, have been employed for the same purpose.

When the sensory muscle-nerves are gravely impaired, as in tabes, the loss of sensibility may be so great that no degree of stimulation will succeed in causing pain. In a case in which inco-ordination was much greater in one leg, forced extension of the calf-muscles in this leg, though unfelt, caused pain in the other leg.

Cases of a mysterious nature are met with in which with normal cutaneous sensation the muscular perceptions are suddenly so much lessened that, as one patient said, 'a poker and a feather seem of equal weight.' Such cases occur in subjects likely to suffer from functional derangements.

TREATMENT.—Muscular anæsthesia usually occurs as part of a wider affection, as in tabes and hysteria, and rarely requires special treatment.

Faradisation of the muscles is the local treatment most useful. It effects powerful stimulation of the afferent muscle-nerves. For the most part the treatment needed is that of the cause. See NERVOUS SYSTEM, Physical Examination of.

MUSCULAR TIC.—A synonym for facial spasm. See FACIAL SPASM.

MUSHROOMS, Poisoning by.—SYNON. : Fr. *Empoisonnement par les Champignons*; Ger. *Pilzvergiftung*.

Poisoning by mushrooms is not a very common occurrence. The varied toxic symptoms produced by the ingestion of mushrooms become more easily explicable when we bear in mind that only a few fungi are apparently poisonous under all conditions. They are *Amanita muscaria*, the fly-fungus, which grows not very plentifully in Great Britain, and contains a poisonous alkaloid (*muscarine*); *Russula integra* seu *emetica* (*Agaricus integer* seu *emeticus*), also not very common; *Boletus luridus* (*B. perniciosis*, *B. bovinus*); and *Amanita phalloides* (*A. bulbosa*, *A. venenosa*, *A. viridis*), to which belong the varieties termed *Agaricus citrinus* and *Agaricus virescens*. These owe their toxic properties to *phallin*, a toxalbumen. Other fungi are poisonous only under special conditions, among which may be named *idiosyncrasy*, and the susceptibility of young children to the toxic effects of mushrooms. The delicious edible morel even has been known to produce fatal results. It must not be forgotten that gastro-intestinal catarrh of a severe character may result from the ingestion of a large quantity of ill-cooked indigestible fungus-tissue; that the highly

nitrogenous tissue of fungi is peculiarly prone to rapid decomposition; and that fungi as a class absorb excretory animal matters, perhaps unchanged. These circumstances may serve to explain some of the apparent anomalies connected with mushroom-poisoning. Some kinds of poisonous mushrooms have their active principle either dissipated or destroyed by the prolonged heat employed in thorough cooking.

ANATOMICAL CHARACTERS.—Evidence of gastro-intestinal catarrh, more prominent in the stomach than in the intestines; signs of cardiac paralysis, or of asphyxia; occasionally fatty degeneration of the liver and other viscera; and minute sub-serous extravasations of blood, have all been noted after death from mushroom-poisoning.

SYMPTOMS.—The symptoms of mushroom-poisoning are of a twofold character: gastro-intestinal irritation, and narcosis due to blood-poisoning. After a meal of poisonous mushrooms has been taken, colic sets in, followed by nausea and repeated vomiting; and diarrhoea eventually supervenes. The onset of symptoms does not as a rule manifest itself till after the lapse of some hours, six or eight or more, from partaking of the fungi. But this period is liable to great variation, and may be much shorter. Fragments of the fungi may be recognised in the fæces; and, indeed, were it not for this, and the history of the case, a diagnosis from violent ordinary gastro-intestinal catarrh would often be impossible. In severe and fatal cases the stools of the patient may become rice-watery in character; the patient becomes algid, collapsed, and cyanosed, with muscular contractions; and in children convulsions are not rarely met with. The sufferer eventually becomes somnolent, and falls into a state of sopor; but this is perhaps not due to a true narcosis.

When the *Amanita muscaria* has been taken, cerebral symptoms are more prominent. The patient appears to be in a state of inebriation; and there frequently appears to be a tendency to dash the head against a wall or other solid object. These symptoms are, however, not exclusively met with in muscarine-poisoning, but may be observed when other fungi have been eaten.

DIAGNOSIS.—The history of the case, and the detection of particles of the fungi in the fæces, are usually sufficient; but in the absence of these a diagnosis from natural disease is perhaps impossible. It has been proposed to test for the presence of muscarine, the active alkaloid of the fly-fungus, by applying a drop of the concentrated or unconcentrated urine to the heart of a frog. Muscarine causes the heart of the animal to stop in the state of diastole. It paralyses the cardiac muscle and stimulates the inhibitory ganglia.

PROGNOSIS.—The patient cannot be considered safe for at least three days, unless the more prominent symptoms have been markedly alleviated. Death may occur at any period between six and seventy-two hours. Recovery is frequent.

TREATMENT.—In poisoning by mushrooms emetics should be promptly administered, to evacuate the stomach, and those which are not of a depressing nature should be selected. The stomach-pump and tube are perhaps of little service, seeing how persistently the particles of fungi adhere to the walls of the gastro-intestinal canal. Oleaginous purgatives, as, for example, a tablespoonful of castor oil in olive oil, may be advantageously administered. Atropine appears to be a direct anti-

ote to muscarine; and digitalis appears to be so in less degree. Atropine should therefore be given in small doses in cases of poisoning by *Amanita muscaria*; and failing this some preparation of digitalis. Should atropine be administered, it would be well to avoid the use of opium; but if atropine be not administered, the exhaustive diarrhoea may have to be combated by the use of opiates combined with astringents.

MYALGIA (*μῦς*, muscle; and *ἄλγος*, pain).—A name for pain in a muscle. See MUSCLES, Diseases of; and RHEUMATISM, MUSCULAR.

MYASTHENIA GRAVIS (*μῦς*, muscle; *ἀσθένεια*, weakness).—SYNON.: Asthenic Bulbar Paralysis.

DEFINITION.—An affection characterised by motor weakness and an abnormal tendency for fatigue to be induced by voluntary effort, which also temporarily increases the weakness, notably in the muscles that have been in action.

ÆTIOLOGY.—There is no special tendency for the malady to occur in families prone to diseases of the nervous system; in no instance has more than one member of a family been attacked, and the subjects of the affection are not, as a rule, neurotic or hysterical. The sexes are equally affected; the disease usually occurs in early adult life, and women are, as a rule, attacked younger than men. Specific fevers, septic processes, absorption of intestinal products (*copremia*), exhausting diseases, parturition, the onset of menstruation, over-exertion, exposure to cold, shock and emotional disturbances have been supposed to be exciting causes.

MORBID ANATOMY AND PATHOLOGY.—No morbid changes have been found in the majority of the cases examined, and we are not yet in a position to be certain of the significance to be attached to such slight defects as have been observed in a few of them. The condition appears to be due to the action of some toxic agent, possibly the result of disordered metabolism, and related to the ordinary phenomena of fatigue which are induced by the products of decomposition from the muscles that have been in action. Some observers have supposed that the poison is introduced into the system, and it has been suggested that it may be the outcome of microbic action. The toxin probably acts on some part of the peripheral motor neurons, either on the cells in the anterior horns of the spinal cord or cranial nerve-nuclei, the peripheral nerves, or the motor end-plates, though some believe that the muscles are primarily affected.

SYMPTOMS.—The great feature of the malady is the readiness with which fatigue is induced on muscular effort, so that muscles that are voluntarily put into action tire rapidly, though they regain power after a period of rest. The onset of the affection is usually gradual, but in a few cases it has been sudden. The weakness is sometimes first noticed in the parts supplied by some of the cranial nerves, in other cases the limbs are first affected, and in others the defect is more or less general from the outset. Muscles in constant action are especially liable to suffer; hence ptosis, weakness

of the external ocular muscles, and similar weakness of the neck-muscles are all common. The ptosis is usually partial, but is quickly increased when the patient looks upwards for a short time; the frontalis may fail to wrinkle the forehead, or having done so the skin quickly becomes smooth again. The external ocular muscles are often weak, they are readily fatigued, and nystagmoid jerking occurs on lateral turning of the eyes to either side. Diplopia is often present, and a special feature observed is that the two images change their relative positions at different times. The pupils are normal and cannot be fatigued. Weakness of the muscles of mastication is common, and may be so pronounced that chewing is impossible. Difficulty of deglutition is nearly always a symptom, and liquids may regurgitate through the nose owing to weakness of the palate. Both the upper and lower facial muscles are usually weak, so that the eyes can only be feebly closed, and pouting the lips and whistling are impossible. The tongue is imperfectly protruded, it is often tremulous, and soon begins to fall back into the mouth; moreover, the patient may be unable to thrust out either cheek with the tongue. The palate is often weak, and may fail to move at all after the letter 'a' has been vocalised several times in succession. The laryngeal muscles have been affected in a few cases. Speech is much altered, so that although the utterance may be clear when the patients begin, it soon becomes indistinct and nasal, and the voice becomes gradually weaker until they have to stop owing to want of breath. The muscles of the neck may be so weak as to be unable to support the head, and similar weakness is met with in the trunk muscles, so that the patient is unable to rise from the recumbent posture without the aid of the arms, and sitting up soon induces fatigue in the muscles of the back. The muscles of respiration may also be weak and the expansion of the thorax very poor, while even slight exertion induces dyspnoea; but apart from this, serious attacks of breathlessness are liable to come on without obvious cause, when the patient is at rest, and may be associated with feelings of faintness or palpitation of the heart. All of the muscles of the limbs may be involved, but it is especially those of the proximal segments that suffer. The myasthenia may be readily demonstrated by making the patients raise the arms above the head, for in a few seconds they begin to fall in spite of every effort to prevent them. After walking a short distance the lower extremities may become so weak that a rest is imperative, while, in some cases, the limbs give way suddenly and the patient falls.

The muscles may be fatigued by a tetanising faradic current so that they cannot be made to contract again until the electrodes have been removed for one or two minutes; this is known as the 'myasthenic reaction.' All of the muscles are, as a rule, well nourished, though in exceptional cases some of them have wasted. The tendon-jerks are usually active, but in some cases it has been possible to temporarily abolish the knee-jerks by repeated blows on the patellar tendon. The sphincters are intact, and there is no defect of cutaneous sensibility or of the muscular sense. There is a feeling of fatigue in the muscles after they have been in action; they sometimes feel stiff, and they may even be tender. In a few cases pain in the head, neck and back, photophobia and giddiness have

been premonitory symptoms; but, as a rule, sensory disturbances are absent. The symptoms are made worse by muscular exertion, emotional excitement, and exposure to cold, and, in females, menstruation and parturition have a similar influence on the course of the disease.

DIAGNOSIS.—When the manifestations of myasthenia are slight they are liable to be mistaken for the effects of *Neurasthenia*. Many of the symptoms might be due to *hysteria*, but the sensory and spasmodic disturbances that are so common in this affection are absent in myasthenia. In chronic *Bulbar Paralysis* there is no ptosis, the ocular muscles are not affected, the tongue atrophies and its muscles and those of the palate show permanent changes in their electrical excitability. Spasticity and muscular atrophy serve to distinguish cases of *Amyotrophic Lateral Sclerosis*, though there may be some difficulty of diagnosis in the rare cases in which the muscles atrophy in myasthenia gravis. Atrophy of muscles also serves to distinguish cases of *Myopathy*, in addition to which some of the muscles may be enlarged, the knee-jerks are commonly absent, and bulbar symptoms never occur. In *Chronic Progressive Ophthalmoplegia* the pupils are often affected, and optic atrophy is frequent; moreover, the limbs, if affected, are either spastic or ataxic, and the motor weakness is not increased on voluntary effort in the way that it is in myasthenia gravis. It may be difficult to exclude *acute poliomyelitis* when the onset of myasthenia gravis is sudden; but the more usual gradual onset, the variability in the intensity of the symptoms, and the absence of muscular wasting are aids to a correct diagnosis.

PROGNOSIS.—In about a third of the recorded cases the disease has been fatal, on an average in eighteen months, but mild cases no doubt pass unrecognised. The symptoms may persist for many years, remissions occur, and some cases probably recover. Weakness of the respiratory muscles and attacks of breathlessness are unfavourable symptoms, and any intercurrent pulmonary affection is a source of danger.

TREATMENT.—Rest is essential; exertion in any form, emotional excitement, and cold must all be avoided; patients must be warmly clad and they ought to be advised not to take cold baths. When difficulty of mastication and of deglutition are symptoms all solid foods must be finely minced, and it may even become necessary to feed by the stomach-tube, a procedure that is not without risk, as one patient died while the tube was being used. Drugs of all kinds have been singularly ineffective; strychnine is no exception, and iron and arsenic are only useful as tonics. Mercury and iodide of potassium have been employed without notable results, as have thyroid and suprarenal extracts. Massage and electrical treatment have also been unsuccessful; indeed, faradism has seemed to do actual harm.

J. S. RISIEN RUSSELL.

MYCETOMA (μύκης, a mushroom).—**SYN.**: Madura Disease or Madura Foot; Fungus-Disease of India.

DEFINITION.—A diseased condition chiefly of the foot and lower part of the leg, occasionally of the hand, and very rarely of the trunk, characterised by enlargement and distortion of the affected parts, due to thickening of the cutaneous tissues, with caries and subsequent fracture of the osseous struc-

tures. Two varieties of the disease have been described, the white, pale, or ochroid, and the black, dark, or melanoid. These are referred to in detail below.

DISTRIBUTION.—Mycetoma is recognised as a distinctive disease of India. It occurs more frequently in Madras, Bombay, and the westerly and north-westerly parts of India than in Bengal proper. This, however, seems to apply more especially to the dark variety; so far as the foot is concerned, the pale form is apparently the one most commonly met with all over India. A few cases have been met with in Italy and North Africa, and three apparently authentic cases of the white and one of the black variety have been described in America.

ANATOMICAL CHARACTERS AND PATHOLOGY. On laying open a characteristic specimen of the disease, the bones are found to be extremely softened, so that they can readily be divided by means of a common knife. The interior of the hand or foot is occupied by a series of sharply defined cavities, some quite isolated, but the majority communicating with one another and with the exterior by a series of complex channels, or sinuses, containing glairy fluid and solid concretions in various proportions. Both cavities and channels are lined by a dense glistening membrane, composed of white fibrous and elastic tissues. The surrounding tissues are generally in a very fatty condition, and, where the disease is of long standing, are more or less completely blended into an indistinguishable mass. So far a common description is applicable to both forms of the disease; but on proceeding to the consideration of the contents of the cavities, great differences present themselves.

Pale form.—The pale or ochroid form is capable of subdivision into several varieties, according to the nature of its morbid products. In the commonest and most characteristic variety the cavities and channels contain masses of spherical bodies like fish-roe, of a pinkish-yellow or white colour, surrounded by gelatinous glairy matter. In certain cases, however, the roe-like bodies are almost or entirely absent, and the gelatinous matter and liquid oil are generally diffused throughout the tissues. In a third and very rare variety the section looks as though besprinkled with grains of red pepper, from the presence of innumerable minute concretions of a bright red hue.

Dark form.—The appearances presented in the dark form of the disease are strikingly different. Here, in place of the roe-like bodies of the previous form, the cavities and channels contain masses of a dark-brown or black colour. These masses vary greatly in size, some not being larger than the normal fat-lobules surrounding them, others attaining to the size of a small orange. The larger masses greatly exceed any of the roe-like masses of the pale variety in size, and their consistence is also much firmer than that of the latter. They are nodulated on the surface, and closely resemble truffles in appearance. On section, they present a more or less distinctly radiating structure, and the interior is generally somewhat lighter in colour than the tuberculated exterior coating. In some cases they are tightly fitted into the cavities in which they lie, but in others they lie loose, and are surrounded by a certain amount of gelatinous matter. The amount of the latter present is, however, much less than in the pale form.

The masses of morbid material in both forms are primarily situated in spaces normally abounding in fat. Long series of them are frequently found lying among the loculi in the subcutaneous tissue, between healthy fat-lobules; others occupy the interior of the bones; and a third series are developed in the pads of fat lying around muscles and tendons. The muscles and tendons in such cases may frequently be found quite intact, although surrounded by masses of the morbid material. Due to this persistence, fracture and crushing of the softened bones often occur, and it is on this that the distortion of the affected part is in many cases in great measure dependent.

MICROSCOPICAL CHARACTERS.—*Pale form.*—The roe-like particles are composed of a nucleus of granular, waxy consistence, surrounded by a radiating fringe. The bright red particles occurring in certain cases of the ochroid form consist in great part of phosphates and carbonates, and contain a considerable proportion of iron. If sections be made through the diseased tissues, and examined microscopically with a low power, considerable epithelial proliferation will be observed at the surface. In the interior, the vessels are much thickened, and scattered throughout the tissues are yellowish bodies of variable size, and irregular or frequently uniform or crescentic in shape; these are surrounded by a radiating zone, and the whole lies in a mass of round cells, many of which may be pigmented, enclosed within a fibrous capsule. On staining by Gram's method and counterstaining with eosin the periphery of the crescentic bodies, which is stained pink with the eosin, is apparently structureless. Within the crescentic bodies, wedge-shaped or ovoid areas are present within which are masses of fine filaments stained purple by Gram's method, and resembling the mycelial filaments met with in *actinomycosis hominis* and in some cases of *actinomycosis bovis*. The radiating zone surrounding the crescentic bodies shows a more or less distinct radial striation, recalling the rays or clubs of actinomycosis. Many of the rays show a fan-shaped expansion owing to branching, and they may be very large, measuring as much as 40–50 μ in length. As is the rule in *actinomycosis hominis* (but the exception in *actinomycosis bovis*), the rays or clubs in mycetoma do not stain by Gram's method. They seem to be in a degenerate condition, but in a fortunate specimen undoubtedly clubs can be demonstrated by staining with orange-rubin or with the Ehrlich-Biondi triple stain (p. 153), thus proving that the radial zone is composed of rays or clubs analogous to those of actinomycosis. Undoubtedly therefore there are many resemblances between the white variety of mycetoma and actinomycosis, as was first pointed out by Vandyke Carter, the chief differences between them being (a) the extremely chronic character of mycetoma, (b) the absence of visceral infection in mycetoma, (c) the fact that animals do not ever seem to be infected with mycetoma, (d) the very large size and frequency of branching of the clubs of mycetoma as compared with actinomycosis, (e) the inefficiency of treatment with potassium iodide. As a matter of fact a peculiar filamentous organism, the *Streptothrix madura*, has been isolated from the white variety of mycetoma. Morphologically and in its staining reactions it resembles the *actinomyces*, but culturally there are many differences. On agar the *Streptothrix madura* forms whitish, round, raised, umbilicated

growths, which do not become yellow and black like *actinomyces*, but may become reddish, and Shattock has suggested that the 'cayenne-pepper' variety of mycetoma may be simply a stage in which this red pigment has been formed. The *Streptothrix madura* will develop in vegetable infusions in which the *actinomyces* refuses to grow; it does not liquefy gelatin as does the *actinomyces*, it will not grow anaerobically, and it is not pathogenic to any animals. See ACTINOMYCOSIS.

Dark form.—Considerable controversy has taken place as to the relation of the black to the white form of mycetoma, some regarding the former as merely a late stage in the latter, while others have suggested that the two conditions are distinct. Clinical observation bears out the latter view, for in the black variety the black particles are present from the earliest stages of the disease, and transition forms between the white and the black have not been met with, as would be expected had the one been a late form of the other. Kanthack, in sections of the black masses, observed at their periphery club-shaped elements, and he therefore believed that the black variety was a late and degenerate stage of the white. Later observations

FIG. 1.—Fungoid Filaments and Capsules obtained after the prolonged maceration in caustic potash of the dark masses of Fungus-disease. $\times 500$.

have, however, shown this view to be untenable. By macerating the black masses in liquor potassae or in 'Eau de Javelle' it is possible to distinguish within them septate fungoid filaments in greater or less proportion. These are sometimes difficult to distinguish, but may generally be detected by allowing portions of the material to soak for some days in liquor potassae. The proportion which the filaments bear to the entire mass, when thus separated, is in any case very small, and in some cases extremely so, for on the completion of the soaking only a very small quantity of colourless flocculi, consisting of masses of branched filaments mixed with empty cyst-like cells, is left behind in the fluid (see fig. 1). The latter has assumed a brown colour from the solution of the dark mass. Boyce and Surveyor recognised these elements as belonging to one of the higher fungi, and they suggested that the black masses are the 'sclerotia' of a fungus, and are analogous to ergot, which is the sclerotium of *Claviceps purpurea*. More recently James H. Wright has succeeded in cultivating a fungoid form or hyphomycete from the black particles. The patient, an Italian woman, came under treatment at the end of 1897 at the Massachusetts General Hospital, with a condition which was recognised as being probably Madura foot. The patient had lived in America for several years, and the disease, which was first noticed in July 1897,

affected the base of the second and third toes on the plantar aspect. There was a small sinus which was discharging a dirty greyish fluid containing some black, hard, irregular granules, like grains of gunpowder. Amputation of the toes and metatarsal bones was performed, and on dissection of the removed tissues an ovoid nodule was found, the size of a pigeon's egg, traversed by a reticulum which divided it into small areas in which were embedded the black granules. Treated with sodium hypochlorite these became bleached and softened, and on crushing, under a cover-glass, were found to consist of a mass of fungoid structures as described by Boyce and Surveyor. Typical septate branching hyphæ were seen showing dilatations or varicosities, the periphery of the nodule apparently being made up of closely-set radiating hyphæ, but no undoubted spore-bearing organs were observed. The black granules were sown on various culture-media, and from a large number a pure growth of a hyphomycete was obtained. On potato a dense, widely-spreading, coherent membrane or layer formed, having a velvety surface and pale brown colour, except at the margins, where it was white. After some time small droplets of a dark coffee-coloured fluid appeared, and the potato became stained a dark brown. In bouillon growth appeared in the form of radiating filaments, so that fluffy balls were produced. In potato-infusion the same growth occurred, but in old cultures black granules made their appearance, consisting of closely-packed spherical or polyhedral cells, and being of the nature of sclerotia. On agar-agar the growth consisted of widely-spreading filaments of a greyish colour, with black 'sclerotia' in old cultures. This hyphomycete was composed of long branching hyphæ $3-8\mu$ in diameter, with transverse septa. No spore-bearing organs were detected, and the organism was non-pathogenic to animals. It is not unlikely that there are other varieties of the disease. The writer has described a case which did not seem to belong to either the white or the black variety.

SYMPTOMS.—Dr. Carter writes: 'As a rule the local indications of this disease are the same for all its forms; for commonly it is not possible to discriminate the several varieties by simple inspection or bare clinical history of the case.' The statements made by the patients as to the mode of origin and progress of these complaints are very various; but, taken generally, they seem to imply that the symptoms are analogous to those usually observed in deep-seated disease of the osseous and adjoining tissues. Eventually a more or less hard lump is felt in the sole of the foot or palm of the hand, or in several places. Generally one or more abscess-like formations occur; and several sinuses are ultimately established, the latter, as a rule, presenting a peculiar mammillated appearance—the 'tubercles,' apparently, of earlier writers. Along with these changes, enlargement and distortion of the affected member take place, but unaccompanied by severe pain. The distortion of the hand is very peculiar—it is shortened and thickened, owing to the destruction of the carpus and metacarpus, and the consequent irregular tension of the extensor and flexor tendons. When the foot is affected, it is found to be considerably increased in circumference, the enlargement seldom extending far beyond the ankle; the foot is prone to run in a line with the leg, and may be everted

or inverted. Discharges set in, more or less offensive, according to the nature of the subjacent degeneration, and the limb becomes not only useless, but a burden to its owner. In this manner the sufferer may go on for from one to fifteen or more years, unless relief be sought in a surgical operation. The disease does not seem ever to give rise to metastatic deposits in the internal organs.

COURSE AND DURATION.—Both forms of fungus-disease run a very chronic course, and often without very materially affecting the general health of the patient; in some cases, however, great emaciation accompanies the disease. With regard to the duration of the malady, it may be stated that cases have been recorded as having existed for various periods up to twenty-six or even thirty years.

TREATMENT.—The only treatment which is of any avail is excision of the affected parts, should the disease come under observation at an early period, or amputation. Potassium iodide, which frequently acts as a specific in actinomycosis, seems to be useless in mycetoma. R. T. HEWLETT.

MYCOSES.—During recent years it has been found that many morbid conditions are due to the growth and development of fungous forms in the tissues; such morbid conditions are known as *mycoses*. There is often little to distinguish them clinically from lesions due to the tubercle-bacillus and other well-known organisms, and hence doubtless many cases remain unrecognised. In certain instances the invading organism is an epiphyte, an organism subsisting under favourable conditions upon the morbid products of some other diseased condition. For example, in phthisical cavities and in the external ear, it has long been known that fungi are occasionally met with. Although frequently epiphytic in the ear, a true 'otomycosis' may be set up as the result of the growth of various organisms—generally species of *Aspergillus* (*niger*, *flavescens*, or *fumigatus*) or of *Mucor*—in the external ear. The disease, which is either acute or chronic, so produced results in a condition of suppurative otitis, and may cause perforation of the tympanic membrane, with more or less pain, tinnitus, and deafness. The diagnosis should not be difficult if the ear be carefully examined with a speculum. Strong alcohol, mercuric-chloride solution, calomel, or boric acid will usually effect a cure. *Aspergillus* may also grow upon the cornea. In the lungs, in phthisical cavities or bronchiectases, fungi such as *aspergillus*, *mucor*, and *oidium* may be epiphytic or secondary. The growth of these is probably a precursor of death in such cases, and is not likely to give rise to symptoms.

There are, however, primary mycoses, chiefly of the lungs, occasionally met with, and it has been proved experimentally that the spores of *Aspergillus fumigatus* are pathogenic to the rabbit. Pneumomycosis or pulmonary aspergillosis is especially a trade-disease in Paris among persons who feed pigeons and other birds artificially. The pigeon-feeder takes the grain into his own mouth, and in feeding the birds inhales any spores that may be attached to the seed. The disease has also been rarely met with under other conditions. The species present seems to be always the *Aspergillus fumigatus*. The clinical signs of pneumomycosis are those of chronic bronchitis and emphysema, or of chronic pulmonary tuberculosis; usually at first the signs are those of bronchitis, with recurrent cough

and greenish purulent expectoration, followed later by consolidation with hæmoptysis, pyrexia, and pleurisy. The diagnosis can only be made by the absence of the tubercle-bacillus from, and the presence of the characteristic mycelium and sporangia of the aspergillus in, the sputum. A mycelium alone is not necessarily aspergillar, it might be actinomycotic. In some instances a double infection with the aspergillus and the tubercle-bacillus takes place. The prognosis in pneumono-mycosis is less grave than in pulmonary tuberculosis, and the disease tends to a spontaneous cure. The treatment must be on general principles, together with iodide of potassium and arsenic. The *post-mortem* changes resemble those of tuberculosis, and consist of whitish tubercle-like nodules, smaller and larger cavities, with surrounding consolidation.

Cases of skin-disease characterised by nodular formation, with subsequent ulceration or suppuration and great destruction of tissue, have been described. In the affected tissues large ovoid bodies with a double contour are present, and these have been regarded as protozoa. Other observers have, however, cultivated a mycelial form in this disease, which may, therefore, be a 'mycotic dermatitis' (*blastomycetic dermatitis*). In its clinical characters the disease is not unlike some forms of cutaneous tuberculosis. In the black variety of mycetoma a fungus-form has been isolated. See MYCETOMA.

The ringworms, favus, and thrush are also examples of mycoses. See TINEÆ.

The so-called 'Mycosis tonsillaris,' consisting of small, white, tough, adherent excrescences upon the pharyngeal mucous membrane, seems to be primarily a keratosis, with secondary infection with bacteria and leptothrix. See TONSILS.

R. T. HEWLETT.

MYCOSIS FUNGOIDES (μύκης, a mushroom or fungus).—**SYNON.** : *Granuloma Fungoides* (Auszitz); *Fibroma Fungoides* (Tilbury Fox); *Lèpre Indigène* (Guérard); *Lymphadénie Cutanée* (Gillot); and probably *Ecceema Hypertrophicum et Tuberculatum* (Erasmus Wilson).

DEFINITION.—A chronic, probably infective, disease of the skin, characterised by a more or less prolonged eczematoid condition, followed by the development of multiple fungating tumours; and almost invariably terminating fatally.

ÆTIOLOGY.—Of the ætiology of mycosis fungoides little that is definite is known. It attacks men with much greater frequency than women, and usually in middle adult life—from forty to fifty years of age; but one case is reported to have begun at the age of five (Port). It is certainly not hereditary. It is believed by many observers to be infectious, though up to the present direct evidence of contagion is wanting, and a specific microbe has not yet been isolated.

SYMPTOMS AND COURSE.—The *first* manifestations of mycosis fungoides may resemble an erythema, an urticaria, a lichen, or the earlier stages of an eczema. They usually consist of well-defined macules, or more extensive erythematous patches, of a pinkish or bright red colour which does not completely disappear on pressure. These may remain discrete, or may coalesce so as to cover large areas of skin, and show a marked predilection for development upon the trunk, scalp and face, while the upper extremities are more frequently and more severely affected than the lower. The lesions are

in the majority of cases notably asymmetrical. Erysipelatous outbreaks, with some elevation of temperature, are prone to occur from time to time, and are usually followed by temporary amelioration of all the symptoms. The patches, which are at first on a level with the surrounding skin, soon become elevated, infiltrated, dense to the touch, and covered with some fine desquamation. They are accompanied by a variable, but generally considerable, amount of burning, tingling, or itching, the latter symptom being in exceptional cases excruciating; papules and vesicles may form upon the patches either spontaneously or as the result of scratching or rubbing. It is almost pathognomonic of the disease that all these manifestations appear and disappear spontaneously with remarkable rapidity, leaving previously affected skin apparently healthy, or at most only slightly atrophic, scaly, or pigmented.

Although partial recovery may thus be said to occur, and complete recovery sometimes seems imminent, the disease invariably progresses to its *second stage*, which is characterised by the deeper infiltration of the derma, and the gradually increasing prominence of the patches, to constitute the *plaques lichénoides* of Bazin. They are irregular in outline, sharply demarcated, bossy on the surface, of a deep purplish or brownish-red colour, and may either be covered with thick scales like a psoriasis, or may ooze and scab like an eczema. These lesions present the same peculiarity as to rapid disappearance as those of the first stage. Another phenomenon noted in a few of the recorded cases—which constituted a marked feature in two of the cases observed by the writer—consists in the frequent appearance of deeply seated lumps indistinguishable from boils, most of which disappear without treatment; some, however, rupture and discharge their pus, but never a necrotic 'core' comparable to that of a true boil. They may, or may not, leave disfiguring scars. When the scalp is involved the hair usually falls rapidly. The nails often become yellow, brittle, and deformed.

After a variable period of time the *third stage* of the disease is attained. It is characterised by the development of peculiar, generally multiple tumours upon skin which is either erythematous or infiltrated; occasionally, however, they spring up from apparently healthy skin. The tumours vary greatly in size, those on the hands being often not bigger than a bean and 'let into' the skin, while on the trunk they may be the size of an orange, or even larger. When situated in considerable numbers upon the face they give a leonine expression very similar to that seen in leprosy. The tumours are sessile, sharply defined, firm, generally of a peculiar deep red colour, but sometimes pale pink or yellowish; they are usually lobulated, and have not inaptly been likened to tomatoes; the epidermis over them is intact, but stretched, tense, and glistening. The amount of pain attending them is variable, but usually they are tender to manipulation. Occasionally tumours appear in the mouth or fauces. In some of the reported cases early and conspicuous involvement of lymphatic glands has been noted, as well as leucocythæmia and enlargement of the spleen, but these appear to the writer to be examples of a separate disorder—a form of lymphadenoma—which it is of importance to differentiate from mycosis fungoides. The same may be said of the form described by Vidal as *Mycosis à tumeurs d'emblée*,

in which there is no eczematoid, pre-mycotic stage, but the growths, which are usually localised, constitute the first and only manifestation of the disease. Such cases are possibly examples of a form of true sarcoma of the skin (Perrin, Hallopeau).

When once developed the tumours may remain unaltered for an indefinite period. More frequently, however, a large number of them spontaneously disappear, leaving the skin either hardened, shrunken, pigmented and desquamating, or else apparently healthy. Fresh erythematous and eczematoid patches nevertheless make their appearance, and fresh tumours, either singly or in crops; in one case (Stelwagon) as many as six hundred were finally present. Of these a certain number ulcerate slowly, the epidermis over them being destroyed; and hideous fungating ulcers are thus formed, from which a thin, ichorous, intensely fetid fluid is discharged. At this stage itching and smarting usually cease, and the tumours become painless. But now for the first time—and the point is one of the most curious and characteristic features of the affection—the general health begins to suffer. Although many of the deep ulcerations may cicatrise, a profound marasmus is gradually established, the patient being usually ultimately carried off by diarrhoea, pulmonary complications, or septicæmia.

DURATION.—The duration of mycosis fungoides varies from a few months to twenty years or more (Besnier); on the average it is from five to six years. In one of the cases observed by the writer, apparent complete recovery took place under treatment, and persisted for more than six months, when a relapse occurred, during which the patient, who was very alcoholic, contracted acute pneumonia, of which he died. It is noteworthy that growths in internal organs have only been observed three times (Duhring, Galliard, Pye-Smith), and in each instance the association appears to have been a coincidence, as the internal tumours did not present the characters of the external ones.

MORBID ANATOMY.—The histological changes found in the early or pre-fungoid stage consist almost entirely of a connective tissue-cell proliferation situated in the corium around the blood-vessels, hair-follicles, sebaceous glands, and sweat-glands, accompanied by a variable degree of dilatation of the blood-vessels of the subpapillary and papillary layers. It is this marked cellular increase which gives to the early lesions of mycosis fungoides their peculiar feeling of infiltration. The cells are mainly of two varieties, namely, large, oval, or fusiform connective-tissue cells, many of which exhibit active mitosis, and numerous smaller roundish cells; but besides these there are a few mast-cells, plasma-cells, and imperfect giant-cells, such as are met with in different proportions in the whole group of the infective granulomata. The epidermis presents certain well-defined changes, such as downgrowth of the interpapillary processes into the corium, interepithelial oedema, and imperfect cornification, but none of these changes can be regarded as in themselves characteristic of this disease. In the fungating tumour-stage the cell-proliferation goes on increasing, but the new cells show a marked tendency to break down, and the connective tissue and elastic fibres to disintegrate, so that a histological examination of one of these tumours reveals an ill-defined mass of broken-down cells and fibres scattered throughout with irregular crenated cells which have not yet broken up. The cells of the

epidermis also become destroyed, and the granulomatous mass is found extending often from the depth of the corium to the surface of the epidermis, and covered only by a thin pellicle of the horny layer, or reaching the surface of the skin and forming the floor of an unhealthy-looking ulcer.

PATHOLOGY.—Divergent views are held as to the pathological group to which the tumours in mycosis fungoides belong. By some authorities they are still regarded as *lymphadenomata* and by others as *sarcoma*; but most recent observers, considering not only their microscopical characters, but also their clinical peculiarities, relegate them to the group of *infective granulomata*. Micrococci have been demonstrated in the tumours and in the capillaries surrounding them; but all attempts to reproduce the disease by the inoculation of pure cultures of these in animals have proved unsuccessful.

More recently McVail, Murray, and Atkinson have isolated a 'short white bacillus' which in rabbits produced certain pathological changes which resulted in death. Their observations have not, however, been confirmed. In the breaking-down granulomatous tissue of this disease we have a medium in which many organisms will readily thrive, even pure cultures of the bacillus of Friedländer having been obtained, so that great care is necessary in distinguishing merely adventitious micro-organisms from a specific microbe. In the blood both ordinary leucocytosis and eosinophilia have been recorded (Nékám), but in the recent cases reported by Galloway and MacLeod, neither an increase in the number of leucocytes nor in the proportion of the eosinophiles was detected.

DIAGNOSIS.—In the later stages of mycosis fungoides no difficulty presents itself as regards diagnosis; but in the earliest stage it may be impossible to differentiate the disease from urticaria, erythema multiforme, or even pityriasis rubra. Its persistence and ulterior developments soon, however, settle the point. In the eczematoid phase the localisation of the patches, their asymmetry, the amount of infiltration and sharp delimitation, their chronicity and greater resistance to treatment, the scantiness of discharge, and their spontaneous appearance and disappearance, generally serve to distinguish the condition from any recognised type of eczema. The early stage of mycosis fungoides has been occasionally mistaken for macular leprosy, but in the former condition anæsthesia and leucoderma are absent; in the tumour stage a bacteriological examination would render the diagnosis from tubercular leprosy perfectly simple.

Framboesia may, apparently, resemble it closely, but is a disease of tropical climates only, the tumours are always small, and there is no pre-mycotic eczematoid stage. The main points of difference from sarcoma and various forms of lymphadenoma of the skin have been already briefly alluded to.

PROGNOSIS.—The prognosis of this disease is necessarily gloomy, but its rate of progress varies widely in different cases. It is only when the final ulcerative and cachectic phase is reached that the patient's condition becomes a very painful or utterly hopeless one.

TREATMENT.—One case of complete and permanent recovery is reported (Bazin) after an accidental attack of erysipelas; inoculation with the streptococci of that disease, in a manner similar to that successfully carried out in the treatment of

intractable cases of lupus, carcinoma, and sarcoma (Fehleisen), appears, therefore, to be a rational and legitimate procedure. Injections of Coley's fluid (mixed toxins of *Streptococcus pyogenes* and *Bacillus prodigiosus*) have proved to be temporarily beneficial.

Arsenic internally, in full and steadily increased doses, has yielded in many cases decidedly beneficial results in the early stages of mycosis fungoides—an observation which the writer is in a position to confirm from practical experience. Its administration hypodermically is probably advantageous, but is seldom tolerated. Mercurials and iodides appear to be deleterious rather than beneficial.

Externally, ointments containing pyrogallol (10 to 15 per cent.) seem particularly efficacious in the eczematoid stage. When tumours are present, the injection of strong carbolic acid into their base has been suggested by Radcliffe Crocker. If ulceration of the tumours has set in, the most scrupulous cleanliness and careful nursing are required. The horrible factor is best controlled by dusting with calol (one part to ten of subnitrate of bismuth), and covering with antiseptic gauze and absorbent wool. Washing with camphorated naphthol has been recommended by Brocq, and lotions of creolin or any other antiseptic are probably useful. Surgical ablation of the tumours has been carried out with success, and without local recurrence, in a few cases in which their number was limited.

J. J. PRINGLE.

MYDRIASIS (*μυδρίασις*).—A preternatural dilatation, and sluggishness or immobility of the pupil. It is the opposite of myosis. See PUPIL, Disorders of.

MYELITIS (*μυελίτις*, the marrow).—Inflammation of the spinal cord. A term that has been much abused, and which is still often wrongly applied to many mere degenerative softenings of this organ. See SPINAL CORD, Diseases of.

MYELOID } (*μυελός*, the marrow).—A form of
MYELOMA } carcinoma, characterised by the presence of giant or myeloid cells. See TUMOURS.

MYOCARDITIS (*μῦς*, a muscle; and *καρδία*, the heart).—Inflammation of the walls of the heart. See HEART, Diseases of.

MYOCLONUS MULTIPLEX.—See PARAMYOCLONUS MULTIPLEX.

MYOMALACIA CORDIS.—SYNON.: Softening of the Heart.—Softening of the myocardium is a result of obstruction of the coronary vessels or their branches by arterial sclerosis, syphilitic arteritis, thrombosis or embolism. The affected area, commonly in the neighbourhood of the apex of the left ventricle, is well defined and softened, possesses the characters of an infarct—red or white—in some stage of its development, with associated pericarditis and endocardial thrombosis. The tissue-elements are degenerated, necrosed, and mutually separated. Occasionally incomplete or complete rupture of the heart occurs. If the subject of myomalacia survive these changes, the affected area becomes fibroid as a result of repair. See HEART, Diseases of, p. 641.

J. MITCHELL BRUCE.

MYOPATHY.—SYNON.: Idiopathic muscular atrophy and hypertrophy; Primary progressive myopathy; Progressive muscular dystrophy.

DESCRIPTION.—Under the term 'myopathy' is included a group of cases in which atrophy of muscles occurs, either alone or in association with hypertrophy of other muscles, and in which the defect originates in the muscle itself, and does not depend on any demonstrable morbid condition of the central or peripheral nervous system. Heredity is a prominent factor in the aetiology of these affections, and young people are almost exclusively attacked.

Most of the cases included under the name 'myopathy' fall into one of three classes: pseudo-hypertrophic paralysis; the juvenile, or upper-arm form of idiopathic muscular atrophy; or the facio-scapulo-humeral form of the same affection.

The cases that belong to the first of these classes are broadly distinguished from those included in the other two by the fact that hypertrophy of muscles rather than atrophy dominates the clinical picture, whereas in the cases that fall into the other two classes atrophy of the muscles is the prominent feature. It must, however, be remembered that in pseudo-hypertrophic paralysis certain muscles atrophy, and that in the other two forms of myopathy some muscles may hypertrophy. Indeed, there are cases that belong to the pseudo-hypertrophic form in which, nevertheless, atrophy of muscles dominates the picture, while if there be any hypertrophy it is so slight, and affects so few muscles, that it is a comparatively insignificant feature in the cases. The main justification for including these with the typical cases of pseudo-hypertrophic paralysis is that a particular combination of muscles is found atrophied in them, which is regarded as characteristic of the pseudo-hypertrophic form.

ÆTIOLOGY.—Heredity plays a most important part in the aetiology of these affections; several members of the same family are commonly affected, and the malady can be traced through several generations. This does not always obtain, however, for undoubted examples of myopathy occur in isolated cases where no other member of the family is known to be affected. The pseudo-hypertrophic form is further characterised by the fact that the transmission from parent to offspring is through females in the family, although the males are usually attacked. This tendency for the disease to manifest itself in boys much more often than in girls, which is so characteristic of pseudo-hypertrophic paralysis, is not met with in the other forms of myopathy, for in them the sexes are about equally affected.

The myopathies are essentially diseases of early life, and they thus differ from the muscular atrophies of spinal origin which more commonly attack older people. Pseudo-hypertrophic paralysis usually commences in childhood. The child may never have walked; more commonly it has learnt to do so, but at the age of four or five years it becomes clumsy on its feet; in some cases the onset is delayed until ten or even until puberty. The other forms of myopathy usually commence at the age of puberty rather than earlier, though the facio-scapulo-humeral form of the disease commonly manifests itself in infancy; indeed, Landouzy and Déjerine in their original description of this variety of myopathy considered that the affection usually begins

at this early age. Few cases of myopathy begin later than the twentieth year.

MORBID ANATOMY.—The morbid changes are limited to the muscles; no defect has been found in the central or peripheral nervous system adequate to account for the profound structural alterations that occur in the muscles. The precise appearances which the muscles present vary according to the form of myopathy that is under observation and the stage which the disease has reached before the fatal termination. Muscles which are still enlarged in a case of pseudo-hypertrophic paralysis owe their size chiefly to increase of interstitial fat and fibrous tissue, rather than to any increase in the size of the muscle-fibres, or their multiplication, for most of the muscle-fibres atrophy, lose their transverse striation, and undergo granular disintegration. Erb, however, contends that the muscle-fibres do hypertrophy, that they subdivide, and that their nuclei multiply; though the fibres subsequently atrophy, disappear, and are replaced by proliferation of connective tissue in which fat appears. This view obtains support from the fact that in portions of muscles removed during life some fibres have been found enlarged, while others have been atrophied, a state of things that has also been met with on *post-mortem* examination. It is said to be rare for the muscle-fibres to show evidence of fatty degeneration, longitudinal striation, fissuring or vacuolation, but changes of this kind have been described in some cases.

The proportion between interstitial fat and connective tissue varies in different cases, and whereas the former may be abundant in the muscles that are still enlarged, the latter may alone be obvious in muscles that have never been increased in volume, or in those that have been enlarged and that have subsequently become reduced in size. In no case, however, is there evidence that the connective tissue is the outcome of fibroid degeneration of the muscle. No changes have been found in the muscle-spindles. Changes in the blood-vessels of the muscles have been described, the walls are thickened, and the lumina narrowed, or even blocked. Babes and Fürstner have described slight changes in the intra-muscular nerves and end-plates, while Gombault has found changes in parts of the axis-cylinders of nerves outside of, but close to, the muscles.

PATHOLOGY.—It is probable that the disease is congenitally determined, and it seems certain that there is a hereditary predisposition for the muscles to succumb in the way that they do; but beyond this we possess no positive knowledge as to how the changes are induced in the muscles. Several views have, however, been expressed with regard to the pathology of the affection. One hypothesis is that the changes in the muscles are primarily interstitial, while the muscle-fibres undergo secondary atrophy. Another view is that the disease begins in the muscle-fibres themselves, and that the fibro-fatty proliferation is secondary to this. Although all observers are agreed that the affection of the muscles is independent of any structural change in the nervous system, Erb contends that the juvenile form of idiopathic muscular atrophy is not a pure myopathy, but is due to functional disturbance in the spinal cord. In view of the structural alterations which he has described in the blood-vessels, Babes regards the changes in the muscles as secondary to the affection of the vessels, and consequently

due to defective nutrition. The reason why certain muscles succumb, while others escape, has been supposed by Babinski and Onanoff to be due to the fact that the muscles that become affected are those that are first to be developed, which accordingly tend to undergo degeneration earlier than those which develop later.

SYMPTOMS.—Although we have considered the myopathies collectively up to the present stage of our description of these affections, it is convenient and of advantage to describe each of the forms separately, in so far as their clinical manifestations are concerned. Even in their clinical aspects, however, the different forms present certain features in common, so that it will be instructive to review the symptoms common to them all, after each of the three forms has been described.

1. *Pseudo-hypertrophic Paralysis.*—The child usually comes under observation because it is clumsy in the use of its lower extremities; it is continually falling, and experiences difficulty in regaining the erect posture, or the first defect noticed may be a difficulty in ascending stairs. These disabilities may appear especially remarkable in view of the fact that the muscles of the legs often seem preternaturally well nourished, owing to the tendency which there is for some muscles to become enlarged. The muscles that are increased in size may remain so throughout the course of the disease; but on the other hand, they may subsequently undergo atrophy, and there are other muscles which atrophy without ever showing any hypertrophy.

The muscles that are prone to become enlarged in the lower extremities are those of the calf, the extensors of the knee, notably the vastus externus, and the gluteus maximus; in the upper extremities, the deltoid, supra- and infra-spinati, and triceps are the muscles usually affected in this way; while, of the trunk muscles, the erector spinæ may be enlarged, though in other cases it is atrophied.

Of the muscles that undergo atrophy it is important to recognise that the lower half of the pectoralis major and the latissimus dorsi are almost invariably affected in this way, and that this grouping of the muscular atrophy is of great value in the diagnosis of this form of myopathy. The atrophy may be so complete as to suggest that the muscles are congenitally absent, and yet the upper half of the pectoralis major stands out prominently, in contrast, when this muscle is brought into action. The serratus magnus is affected in some cases, and the biceps commonly wastes. In the lower extremities the muscles that usually atrophy are the flexors of the knee, and the adductors and flexors of the hip.

While certain muscles hypertrophy, and others atrophy, there are others that remain unaltered. This is the rule to which there are but few exceptions in the case of the muscles of the face, though the masseters and tongue are sometimes enlarged. The muscles of the neck also usually escape, as do the trapezius and rhomboids. The intrinsic muscles of the hands are nearly always intact, and the muscles of the forearm usually escape also, though the supinator longus may be hypertrophied or atrophied, and slight enlargement of the extensors of the wrist is sometimes met with.

All the affected muscles, whether atrophied or hypertrophied, are weak; that this is so in the case of the latter class of muscle is well seen in the calf, for though these muscles may be greatly enlarged,

the patient is unable to stand on tip-toe. The most characteristic defects which are due to the muscular weakness are certain deformities, notably of the spine, an alteration in the attitude and gait, a peculiar way in which these patients rise from the recumbent to the erect posture, and later on their inability to do so at all, even by the aid of the dodges which they formerly employed. In the sitting posture there may be no notable deformity of the spine, or there may be a pronounced kyphosis shared by the whole length of the spinal column; but when the patient is in the erect posture a pronounced lordosis commonly appears in the lumbar region, while there is compensatory kyphosis in the cervical and upper thoracic regions of the spine, and the shoulders are thrown unduly backwards, so that a plumb-line dropped from the most prominent part of the convexity of the spine falls well clear of the sacrum.

The patient stands with his feet far apart, so as to rest on a wide base, and in walking he waddles from side to side in order to keep the advancing foot clear of the ground, while the knee is brought forward in advance of the foot when the extensors of the knee are feeble. He experiences difficulty in rising from the sitting posture, chiefly owing to weakness of the extensors of the hip and knee. In attempting to get up from the recumbent position he first rolls over to one side, then draws up his legs to the trunk and twists his body over so as to get on to his hands and knees. He next puts his head down between his arms and gradually extends his knees until he rests on his hands and toes; the hands are then brought nearer and nearer to the feet, which are made the fixed point, and first one and then the other hand is rapidly moved from the ground to his knees, and he then proceeds to climb up himself by placing each hand in turn higher and higher up his thighs, and finally by a sudden movement of his shoulders backwards he attains the erect posture.

With the progressive weakness which occurs in the affected muscles, be they atrophied or hypertrophied, the electrical reactions, which are at first normal, become altered, so that the amount of contraction of the muscles which results when they are stimulated both by faradism and galvanism becomes progressively less, until there are no muscle-fibres left to give a response; but the reaction of degeneration is never present. Fibrillary tremors of the muscles scarcely ever occur, and there is never any spasticity. Contracture of the calf-muscles, which is often an early manifestation, and which leads to talipes equinus, is due to contraction of fibrous tissue, and not to any spasm of the muscles. The knee-jerks are lost or retained according to whether the extensors of the knee are or are not affected, and from Sherrington's experimental observations in the monkey it would appear to be the condition of the vastus internus that is important in this connection. As the extensor muscles become weaker, so the knee-jerk becomes more feeble until ultimately it is abolished. Ankle-clonus is never present. The superficial reflexes persist as long as the muscles on which they depend are capable of responding. There is never any blunting of cutaneous sensibility. The sphincters escape, but may possibly become affected in the final stage of the malady.

2. *Juvenile or upper-arm form of idiopathic muscular atrophy.*—This form was first described by Erb. The disease usually manifests itself about

the time of puberty, the atrophy commencing in the muscles of the upper arm and those of the shoulder-girdle. The muscles that are earliest affected are the biceps, triceps and supinator longus, and these are followed by the pectoralis major, latissimus dorsi, serratus magnus, and trapezius. The trapezius is liable to be atrophied throughout its whole extent, and there is not the tendency for its upper portion to escape in the way that it does in the muscular atrophies of spinal origin. The sternomastoid is also affected in some cases, while later in the course of the disease the muscles of the trunk, the glutei, and the muscles of the thigh, notably the quadriceps-extensor group, suffer. The flexors and adductors of the hip may also be weak, and in some cases the anterior tibial group and the peronei are involved. The deltoid and supra- and infra-spinati usually escape, and the rule that has but few exceptions is that the muscles of the face, those of the forearm, with the exception of the supinator longus, and the intrinsic muscles of the hand also escape. Certain noteworthy deformities of the spine result in consequence of the weakness of the trunk-muscles and glutei. If the erector spinæ is alone affected there is marked lordosis, when the patient stands, so that a plumb-line suspended from the most prominent part of the cervico-dorsal spines drops clear of the sacrum; but when the glutei are also weak the pelvis becomes tilted forward, and the sacrum projects so far back that the plumb-line is no longer able to clear it. In either case the lordosis is replaced by kyphosis when the patient sits down, provided the recti muscles of the abdomen be intact; but the lordosis persists if the recti are weak, as these muscles are then unable to flex the spine by approximating the thorax and pelvis in front.

3. *The facio-scapulo-humeral form of idiopathic muscular atrophy.*—This affection usually commences at the time of puberty, although there is commonly a history that the patient has never been able to close the eyes properly, or whistle. Whether the disease commences in infancy or not, the face is usually the first part affected, and the first muscles to suffer are the orbicularis palpebrarum, and the orbicularis oris. The patient is accordingly unable to close the eyes tightly; the lips are prominent and everted, and cannot be pursed, as in whistling. The levator anguli oris also becomes affected, so that although the angles of the mouth can be retracted, the upper lip cannot be elevated; or the zygomatici may suffer, so that instead of the upper lip being drawn outwards and upwards, when the patient smiles, the lip is drawn upwards only. The forehead commonly looks as smooth as ivory, the expression is characteristically sanctimonious, and when attempts are made to perform facial movements the angles of the mouth are depressed so that the patient looks as if about to cry. Nearly every muscle of the face may in time become affected. A point that is of considerable importance in diagnosis is that the muscles of the eyeballs and tongue escape, despite the fact that the orbicularis palpebrarum and orbicularis oris are affected.

The muscles that next become atrophied are those about the shoulder-girdle and upper arm, and later in the course of the disease the extensors of the wrist and fingers may also be affected. The supra- and infra-spinati escape, as do the flexors of the wrist and fingers, and the intrinsic muscles of the hand. The muscles of the trunk and lower

extremities are attacked in the same way as in the form of myopathy in which the face escapes, and the same deformities of the spine and thorax, and alterations in the character of the gait are met with, so that a separate description of these defects would be superfluous.

Features that the myopathies possess in common. The three forms of myopathy have certain characters in common. They are all progressive. In all of the forms of myopathy, whether there be hypertrophy of any of the muscles or not, some muscles may be unduly hard, in consequence of replacement of the muscle-fibres by fibrous tissue, though this does not obtain in every case. The affected muscles, whether hypertrophied or atrophied, become progressively weak, and their response to both forms of electrical current becomes more and more feeble, until finally there are no muscle-fibres left to respond; but there is never any qualitative change in the mode of response to galvanism such as constitutes the reaction of degeneration. Fibrillary tremors are so rare that most writers on this subject state that they never occur. Although there may be contraction of muscles, consequent on shortening of the fibrous tissue which replaces the muscle-fibres, there is never any spasticity such as commonly accompanies the chronic muscular atrophies of spinal origin. The knee-jerks persist, as long as there are a sufficient number of muscle-fibres intact in the extensors of the knee, and the vastus internus is probably the muscle whose state of nutrition is of the most importance in this connection. The superficial reflexes also persist as long as the muscles on which they depend are intact. There is never any blunting of sensibility; tactile, painful and thermal impressions are all normally perceived. The sphincters remain normal throughout the course of the disease, except, it may be, in the final stages of very advanced cases, when there may be loss of control over both sphincters.

DIAGNOSIS.—The detection of hypertrophy of any muscles makes it certain that the case is myopathic in nature, and that the muscular atrophy is not due to affection of the spinal cord or peripheral nerves. Valuable information is also derived from the combination in which the muscles are atrophied, and, in the absence of hypertrophy of any muscles, diagnosis rests largely on which muscles are atrophied. In the myopathies the muscles of the proximal segments of the upper limbs suffer earliest and in greatest degree, while those of the distal segments usually escape; whereas in the myelopathies muscles of the distal segments of the upper limbs most commonly succumb first, and even when the affection begins in the shoulder, the deltoid is the muscle that atrophies first, whereas this muscle usually escapes atrophy in the myopathies, in spite of the fact that so many other muscles about the shoulder-girdle are affected. Another fact of importance is that the trapezius may become atrophied early, and throughout its whole extent, in the myopathies, whereas the upper portion of this muscle usually escapes to the very end in cases in which the muscular atrophy is due to affection of the spinal cord. The escape of the muscles of the eyes and tongue, despite the fact that the orbicularis palpebrarum and orbicularis oris are affected, is of great value in distinguishing the facial affection of the facio-scapulo-humeral form of myopathy from paralysis due to affection of the nuclei of the third and twelfth nerves; for if the paralysis of the orbicularis palpe-

brarum be due to a lesion of the third nucleus, the ocular nerves are concomitantly affected, and lesions of the hypoglossal nucleus occasion paralysis of the tongue in conjunction with the orbicularis oris. The presence of spasticity associated with exaggerated knee-jerks and ankle-clonus indicates that the muscular atrophy is of myelopathic origin. Extension of the toes when the plantar surface of the foot is stimulated is of similar significance. The absence of these phenomena does not, however, exclude the possibility that the muscular atrophy is due to disease of the spinal cord. When fibrillary tremors are present in the muscles it is highly probable that the disease is myelopathic, though this feature does not absolutely negative a myopathic origin of the muscular atrophy. The age of the patient is a further aid in diagnosis, for the myopathies occur in children and young adults, while the muscular atrophies of spinal origin, as a rule, belong to the later degenerative periods of life. More important still is the hereditary tendency of the disease, as it is most exceptional to have transmission from parent to offspring, or affection of more than one member of a family, in the muscular atrophies of spinal origin.

The peroneal type of muscular atrophy resembles the myopathies in that several members of a family are affected, in addition to which it may be hereditary, and the manifestations begin early in life. The atrophy, however, commences in the peronei and other muscles of the legs below the knees, and the small muscles of the hands become similarly affected. Moreover, there may be pain, cutaneous sensibility is commonly blunted, and vaso-motor changes occur in the skin.

In subacute poliomyelitis, except the most chronic form, paralysis precedes wasting of the muscles, and there is commonly some tendency to recovery, although in other cases the disease is progressive. There is a random distribution of the atrophy instead of the muscles being affected in special combinations, as is the case in the myopathies. Moreover, the affected muscles commonly show the reaction of degeneration on electrical stimulation.

Atrophy of the muscles of the shoulder and upper arm, consequent on a lesion of the fifth and sixth cervical nerve roots, is distinguished by the fact that all the muscles affected are supplied by these roots; and, moreover, all the muscles in their supply are usually affected, instead of some of them escaping, as is the case in the myopathies. In a lesion of the fifth root there is paralysis with atrophy of the supra- and infra-spinati, clavicular portion of the pectoralis major, deltoid, biceps, brachialis anticus, and supinator longus; while damage to the sixth root results in similar affection of the sternal part of the pectoralis major, the latissimus dorsi and triceps. The muscles show the reaction of degeneration on electrical stimulation. A history of pain and the presence of anæsthesia may further help to distinguish cases of this kind from muscular atrophies of myopathic origin.

The exclusion of syringomyelia is based on the fact that sensibility is blunted in that disease; indeed there may be a dissociation of sensibility, so that although painful and thermal impressions are no longer perceived, tactile impressions are nevertheless correctly recognised. Moreover, the patients are subject to trophic disturbances of the skin, spastic phenomena appear in the lower extremities, lateral curvature of the spine usually occurs, nystagmus is

common, and the small muscles of the hands are those that are usually atrophied.

PROGNOSIS varies in the different forms of myopathy. The subjects of pseudo-hypertrophic paralysis die before they reach the age of twenty, commonly as the result of bronchitis or pneumonia; suffocation results as the expiratory muscles are too feeble to expel the secretion from the lungs. Prognosis is, however, favourable in the irregular forms of pseudo-hypertrophic paralysis which attack adults; but, strictly speaking, many of these are cases of idiopathic muscular atrophy in which some muscles are hypertrophied.

The outlook in the other two forms of myopathy is much more favourable than in the ordinary form of pseudo-hypertrophic paralysis, for these affections are compatible with preservation of life for a good many years. Indeed, Erb believes that the malady is sometimes arrested by treatment. Whether as a result of treatment or not, it is certain that some cases do remain stationary for many years. The age at which the malady commences has a distinct influence on prognosis in the facio-scapulo-humeral form, for the cases that begin after puberty are more likely to become arrested than are those that begin in childhood. When there is arrest of the disease, muscles that are atrophied do not recover, but there is no further progress of the atrophy in those that are not already completely destroyed, nor do muscles hitherto unaffected show any tendency to waste.

TREATMENT.—It is important to maintain the patient's general nutrition at as high a standard as possible, in the hope that the nutrition of the affected muscles may also be favourably influenced. With this object in view, a liberal dietary must be provided, and it ought to be supplemented by cod-liver oil, malt, and tonics such as arsenic and iron. The drug that is administered with most hope that benefit may accrue from its use, in this as in other forms of muscular atrophy, is strychnine, which may be taken by the mouth, but which is supposed to be more efficacious when given by subcutaneous injection. Of local measures, in the treatment of these cases, both massage and galvanism are of great importance. By their aid we may hope to influence favourably the nutrition of the muscles, and thus retard, or arrest the progress of the atrophy, so that these measures should be persevered with, no matter how discouraging the result may seem. Passive movements are of great service in preventing contracture, and when shortening of muscles has already occurred tenotomy is indicated, where there is reason to suppose that this measure will enable the patient to use the limbs again. This is especially important in regard to the talipes equinus that is so common in pseudo-hypertrophic paralysis, as the correction of this deformity may enable the patient to resume walking exercise, for it has been observed that these patients usually become rapidly worse when they are no longer able to walk. Although patients suffering from the different forms of myopathy must be encouraged to take exercise, this must not be in sufficient amount to cause fatigue; indeed, any depressing influence, whether physical or mental, is to be avoided. When the patients become bedridden it is important to avoid contracture and fixation of parts in awkward positions, so that the trunk should be propped up to prevent such curvatures of the spine as can thus be avoided; and the limbs ought to be kept, as far as

possible, in suitable positions. As so many of these patients succumb to pulmonary affections, such as bronchitis and pneumonia, great care must be taken to keep them warmly clad, and to avoid exposure such as may occasion a chill.

J. S. RISIEN RUSSELL.

MYOPIA (μύωψ; from μύω, I close or blink; and ὤψ, the eye).—That form of *ametropia*, or error of refraction, in which, owing to a high refractive index of the dioptric media, or excessive convexity of the refracting surfaces, or abnormal elongation of the antero-posterior axis of the eyeball, parallel rays of light converge to a focus in front of the retina, and form therefore circles of diffusion upon it. It is the opposite of *hypermetropia* (see *HYPERMETROPIA*), and is sometimes called *brachymetropia* (βραχύς, short; μέτρον, a measure; and ὤψ, the eye), or *hypometropia* (ὑπομέτρος, below the measure). See VISION, Disorders of.

MYOSIS (μύω, I shut).—A preternatural contraction and sluggishness or immobility of the pupil. The opposite of mydriasis. See PUPIL, Disorders of.

MYOSITIS (μῦς, a muscle).—Inflammation of a muscle. See MUSCLES, Diseases of.

MYOTATIC (μῦς, a muscle; and τατικός, extended, tense).—Tense-muscle irritability or action. 'Myotatic irritability' and 'myotatic action' are terms introduced by Gowers, and occasionally employed as designations for the phenomena termed 'tendon-reflex,' or the conditions under which they occur. The term 'myotatic' was proposed as involving no theory of the nature of these phenomena, but merely the unquestionable fact that they can only be elicited when the muscles are in a state of moderate extension, usually passive. See SPINAL CORD, Diseases of.

MYXCEDEMA (μύξα, mucus; and οἶδημα, a swelling).

DEFINITION.—Myxcedema is a disease depending on loss of function of the thyroid gland, characterised by remarkable changes in physiognomy, and associated with many signs of nervous disorder. It appears to be identical with cachexia strumipriva (Kocher) and sporadic cretinism (Curling).

ÆTIOLOGY.—That the disease depends on loss of function of the thyroid gland is shown by the facts that the thyroid gland is constantly found to be atrophied, that a condition similar to myxcedema can be artificially produced both in man and the lower animals by extirpation of the gland by operation, and that the symptoms of the disease can be removed by the administration of thyroid substance from one of the lower animals, and that they return when treatment is suspended. In some cases atrophy of the gland has been preceded by hypertrophy, and sometimes myxcedema has succeeded exophthalmic goitre.

The cause of the atrophy of the thyroid gland is at present unknown. Among common antecedent conditions have been observed profuse hemorrhage, menorrhagia, persistent and severe vomiting, chronic diarrhoea, frequent child-bearing, prolonged lactation, continued mental worry, shock from injury or accident, acute rheumatism and erysipelas.

As in the case of exophthalmic goitre, females are affected more than males (7 to 1). The disease

may occur at any age. In children the malady specially affects growth of body and development of intellect, and in consequence differs somewhat from the adult form, and is described as sporadic cretinism. In adults the disease usually comes on after the age of thirty. Out of 156 cases in which the age at which the disease began was noted, 5 commenced before 20, 24 between 20 and 30, 50 between 30 and 40, 47 between 40 and 50, 24 between 50 and 60, 6 over 60. Thus nearly two-thirds of the cases originated between 30 and 50. As regards the ages at which the disease is met with, it may be observed that up to middle life the disease increases in frequency, after which it gradually diminishes again. Of 231 recorded cases, only 5 were under 25, all females, 34 were between 25 and 35, 60 between 35 and 45, 60 between 45 and 55, 71 between 55 and 70, and 2 over 70. Social position appears to be without influence. Of 109 affected females, 91 were married and 73 had borne children. In a significant number of cases the disease has been found to affect several members of the same family, and there may be direct transmission from father or mother.

ANATOMICAL CHARACTERS.—The body is increased in bulk and there is an excess of subcutaneous fat, and of fat elsewhere throughout the body. A slight degree of anasarca is not uncommon, and passive effusions into the serous cavities have been frequently noted. The thyroid gland is reduced in size, and has been variously described as pale yellowish-white, or buff-coloured, firm, tough and indurated, fibrous and structureless. Atheroma of the larger arteries and interstitial changes in the kidneys are not infrequent. Tuberculosis has been present in a number of the recorded cases. Occasionally the pituitary body has been hypertrophied. The change in the structure of the thyroid gland appears to be of one kind in the very large majority of cases. An early stage of small-celled infiltration of the walls of the vesicles is accompanied or followed by epithelial proliferation in the vesicles themselves. Later on, the gland becomes converted into a delicate fibrous tissue through which are scattered clumps of small round cells, epithelial cells and colloid masses, clearly the remains of the vesicles, until finally the gland-substance is almost entirely replaced by dense fibrous tissue, in which only a few small islets of round cells can be detected. In some parts of the gland the changes may be more advanced than in others. The changes in the skin and tissues which bring about the striking physiognomy of the disease are secondary to the affection of the thyroid. A remarkable overgrowth, consisting in part of hyperplasia, in part of retrograde degeneration of connective tissue, is found in several or all parts of the body. The fibrillar constituent of ordinary connective tissue is everywhere increased, and its elements unnaturally defined, so that the bundles are largely broken up into individual fibres; the corpuscles are enlarged and multiplied; and the interstitial cement is augmented. In the skin there occurs a nucleated fibrous growth in the tissue outside the coiled tubes of the sweat-glands, the lumina of which are obliterated by the swelling and proliferation of the epithelium. A similar change may be observed in the sebaceous glands, which are represented by irregular masses of nuclei. The hair-follicles are surrounded by a cellular growth, external to which nucleated fibrous tissue sometimes develops. Vacuolation of

a considerable proportion of the fat-cell nuclei has been observed. The same sort of interstitial expansion is found in the mucous membranes, in glands of all kinds, in muscles, and in the central ganglia of the nervous system, subjecting the proper structural elements of each tissue to destructive pressure. It is most developed of all, perhaps, in the outer coat of arteries. In the brain, in some cases there appears to be a general increase of neuroglia, and a very considerable growth of the connective tissue around all the vessels. It must be observed that these appearances, while present in the case of persons dying in the full development of the disease, are less marked or absent in cases where the characters of the disease have been altered by treatment or by changes preceding death.

The name myxœdema was given to this disease by Ord, because in his first investigations he found that the skin yielded a greatly increased amount of mucin. Later chemical investigations have shown that increase of mucin is by no means a constant, and seldom a marked, feature. In acute experimental myxœdema in animals, however, a decided increase of mucin has been observed.

SYMPTOMS.—In myxœdema the physiognomy is the first characteristic. The face is swollen in every feature, so as to suggest the existence of renal disease to an inexperienced observer. The distribution and quality of the swelling are however strikingly different from what is observed in common dropsy. The swollen skin is singularly waxy-looking and anæmic. The œdema is resilient, does not pit on pressure or shift by gravitation, and affects dependent and non-dependent features equally. Thus the upper and lower eyelids, and the upper and lower lips are uniformly enlarged; the *alæ nasi* are thickened and broadened; the ridges of expression are blurred and coarsened, or the lines obliterated. There is a characteristic raising and arching of the eyebrows to compensate for the swelling of the lids. The cheeks are overspread with a well-defined dull pink flush in vivid contrast with the pallid skin around.

The conditions observed in the face prevail throughout the body. There is a general increase in bulk and weight, and the abdomen is large and pendulous. The skin is thickened, dry, scaly or branny, and rough to the touch, perspiration being infrequent or absent. The hairs begin to fall out at an early stage, and are ragged and broken. The scalp is scurfy and often bald, the eyebrows thin. The teeth decay, break, or fall out. The hands lose all shapeliness and expression, and become broad and clumsy looking, or 'spade-like.' The feet are similarly affected, and both are cold and often purple or livid. Warty growths and moles are not infrequently present on the body and limbs as well as on the face. There is often a decided fulness above the clavicles. Slight œdema about the feet and ankles is common. The tongue is large and thick.

The nervous system is early affected. An ever increasing hebeticity involves sensation, voluntary movement, and intellect. The face wears a fixed heavy expression; the speech is slow and laboured, though not slurred or slovenly; the voice is monotonous, like that of an automaton, and of a peculiar so-called 'leathery' tone. Sensation is slow, yet finally sure. The movements of the limbs are slow, clumsy, and languid; the maintenance of fixed attitudes requires much effort, and the head, for

example, is apt to drop forward on the chest; sudden falls are not infrequent, in some cases leading to rupture of tendons or fracture of the patella. The walk is waddling, and the movements have been compared to those of the hippopotamus. Frontal or occipital headache, rheumatic pains, numbness, tingling or pricking in the extremities are common subjective sensations. In the operations of the intellect, thought and volition are again slow. Patients complain of being unable to perform the daily actions of life with their natural expedition. Nevertheless what they do is well done, and they are acutely conscious of their slowness. In conversation ideas come deliberately, and are tardily expressed. To write a letter occupies an hour, where it would before have taken ten minutes. Yet the language is correct, and the caligraphy unchanged. There is, in fact, an unwieldy state of mind as of body. Impairment of memory, especially for recent events, occurs early in the disease. The temperament is not infrequently placid or torpid, but irritability or fretfulness occurs from time to time in a large number of cases. Excessive drowsiness during the day, with or without sleeplessness at night, is not uncommon. Delusions or hallucinations are present in many cases. Hearing is very frequently affected, deafness occurring on one or both sides, and there are sometimes noises in the ears. Perversions of taste and smell are not uncommon.

The temperature of the body is almost always subnormal, ranging between 98° and 94° F., or even less. Most patients complain of constant chilliness, without appearing to estimate readily any changes of external temperature. The pulse-rate is either normal or slow. The urine is usually lowered in specific gravity and deficient in urea; but as a rule contains no albumen, sugar, or casts. In the later stages albuminuria usually occurs. The catamenia are very frequently irregular. Sometimes there is amenorrhœa, sometimes menorrhagia, sometimes sexual feelings are in abeyance. In many cases there is a decided tendency to hæmorrhages, which may take place from the gums, throat, nose, or uterus. The extraction of a tooth has been followed by prolonged bleeding from the socket and gums. In the later stages the mind often becomes entirely unheinged. The patient becomes morose, suspicious, and more fretful and irritable; delusions or hallucinations ensue if they have not already occurred. A considerable number of cases drift into asylums, with the usual symptoms of acute or chronic mania, dementia or melancholia. Death comes sometimes by coma, or asphyxia, or with the signs of uræmic poisoning, or by inanition, but in the majority of cases is caused by intercurrent disease.

DIAGNOSIS.—As a rule there is little or no difficulty in recognising the disease when it is well established. The malady was originally confounded with chronic Bright's disease, but there are numerous points of distinction. Scleroderma is sometimes mistaken for myxœdema, but the hide-bound skin and mask-like face are quite unlike the condition produced by the latter disease. Acromegaly, with the enlargement of the extremities, has also distinguishing features. See ACROMEGALY.

PROGNOSIS.—The progress of the untreated disease is slow and far from uniform. There may be many alterations in the symptoms, and the swelling of the skin and the nervous disorder may vary considerably from time to time, so that occasionally

the disease may seem to disappear. But unless the remedy is employed, the ultimate prognosis is unfavourable. The disease has been known to last in untreated cases as long as twenty years, but even then life has been cut short by the disease. Since the introduction of the highly successful mode of treatment by means of thyroid gland the prognosis of the disease has become very different. Even after the disease has been in existence a great many years the treatment is in most cases successful in removing the symptoms. The most unfavourable cases are those in which insanity has supervened.

TREATMENT.—Myxœdema is very amenable to treatment. It was shown by Schiff and others that the cachexia following thyroidectomy in animals could be temporarily prevented or diminished by transplanting a thyroid gland from another animal. As, however, the gland did not take root the benefit did not last long. Gley and Vassale next tried the effects of injections of thyroid juice for the same purpose. The first to try such subcutaneous injections in cases of myxœdema was George Murray, of Newcastle, and the results he obtained quickly showed that a most potent remedy had been found for the disease. The next step was the discovery made independently by the present writer, by E. L. Fox, of Plymouth, and by Howitz, of Copenhagen, that the disease could be equally successfully treated when thyroid-gland substance, or an extract prepared from it, was given by the mouth. The last mode of treatment is that which is followed at the present day, and it has been proved to be thoroughly successful in removing the symptoms of the disease.

In starting thyroid-treatment in a case of myxœdema it must be borne in mind that in this disease the reaction of the remedy is much greater than in health. Small doses should invariably be given at first, such as three to five minims of *Liquor Thyroidei* (B.P.), or three to five grains of *Thyroideum Siccum* (B.P.) once a day. Corresponding doses may be given of any of the various preparations, such as thyroid tablets or capsules, and thyro-colloid, which are prepared by various manufacturers. In many cases larger doses need never be given, but in some cases it may be necessary gradually to increase the dose. It is seldom necessary, however, to give more than the equivalent of ten minims of the *Liquor* twice a day. When the symptoms of the disease have disappeared the dose may be decreased. A small dose once or twice a week may prove sufficient to keep the patient in health. If the remedy is suspended for any length of time the symptoms of the disease will slowly return. It must be explained to the patient that it will be necessary to continue the remedy during the whole of life. Certain unpleasant symptoms are apt to show themselves to a greater or less extent during the cure, but these are most likely to occur when the remedy is being pushed, and as a rule indicate that too large a dose is being employed. Gastro-intestinal disturbance may arise with such symptoms as loss of appetite, fetid breath, burning in stomach, thirst, nausea, vomiting, pains in the bowels, and diarrhœa. Frontal headache—sometimes severe and persistent, pain in the back, rheumatic pains and aching in the limbs, burning, tingling, or smarting in the fingers and toes, itching of the skin—sometimes to an intolerable degree, erythema, urticaria, general œdema, and desquamation of the hands

and feet are not uncommon. The temperature, previously subnormal, may become febrile, and the heart-beats rapid and sometimes irregular; while the patient suffers from palpitation. Great care should be taken to keep the patient at rest in the recumbent position if there are any signs of failing heart, as sometimes death has occurred from cardiac failure during the process of cure. Attacks of faintness or of angina have been observed. Giddiness, sometimes directly after taking food, epileptic

attacks or temporary loss of consciousness, emaciation, prostration, sleeplessness, restlessness, sweating, trembling, and swelling of the parotid and submaxillary glands are among other symptoms which have been occasionally experienced. These untoward symptoms will probably prove very rare when the remedy is given cautiously in small quantities. The dose should be diminished at once should undesirable symptoms be produced.

HECTOR MACKENZIE.

NÆVUS.—See TUMOURS.

NAILS, Diseases of.—SYNON.: FR. *Maladies des Ongles*; GER. *Krankheiten der Nägel*.

The ungual diseases may be conveniently grouped into: A. Hypertrophies; B. Atrophies; C. Dys-trophies; D. Morbid conditions accompanying certain cutaneous affections; and E. Parasitic diseases.

A. Hypertrophies.—1. *Simple Hypertrophy* of the nail-substance (onychauxis) is a comparatively rare condition. When it occurs the nail is enlarged, and is both thicker and harder than in the normal state, and this excessive nail-formation is due to an over-activity or an increase in size of the nail-matrix. This condition is found in the clubbed fingers of thoracic disease, and in acromegaly and gigantism. See FINGERS, CLUBBING OF.

2. *Hypertrophy with deformity* of the nail is more common than simple hypertrophy and results in the troublesome conditions known as *ingrowing toe-nail*, *claw-nail*, and *ram's horn-nail* (onychogryphosis), names which sufficiently indicate the more common shapes which the deformed nail assumes. In these affections the nail-substance becomes peculiarly hard, from a closer cohesion of its component cells, its healthy transparency is lost, and it becomes opaque and assumes a dirty brownish colour, and the surface becomes roughened by the presence of longitudinal and wavy transverse ridges.

ETIOLOGY.—These deformities of the nail are most frequently met with in elderly bedridden people, but they may occur at any age. Intermittent external pressure from badly fitting boots is a common cause of these conditions, but of equal importance is the neglect of proper cleanliness of the nails, by permitting irritant substances to accumulate between the nail and the nail-bed, which set up an hyperplasia of the nail-substance. Certain chronic nerve-affections such as myelitis, peripheral neuritis, and tabes dorsalis may be associated with the formation of an imperfect nail-substance, and may even produce an excessive growth and deformity of the nail.

PATHOLOGY.—By pressure or injury a widening of the nail-fold is produced which allows the formation of a thicker nail. At the same time the nail-bed is irritated and a horny mass forms on it below the nail, which acts as a barrier to the forward growth of the nail, and by raising it up, more or less determines the various degrees of deformity. The pressure of the ingrowing or claw-nail on the neighbouring soft parts produces in them a condi-

tion of lessened resistance, and a greater liability to secondary inoculation with septic organisms, which play a most important rôle in the evolution of the various onychopathies.

SYMPTOMS.—Pain—usually intermittent, but in some cases constant—is the most important symptom of ingrowing toe-nails. As a rule it is so severe that walking is rendered impossible. The pain results not only from pressure, but also from exposure of the sensitive nail-bed, which occurs when the nail is much raised up. If secondary inoculation take place in the neighbouring soft parts, suppurative, œdema, gangrene, and even sloughing of the nails may occur (*onychia* and *paronychia*).

TREATMENT.—In the milder forms of onychogryphosis, such as ingrowing nails, it is often sufficient to cut the nail as short as possible, and to insert pledgets of gauze impregnated with some antiseptic lotion between the edge of the nail and the inflamed skin. If the lateral pressure by the nail be severe it is necessary to press down the skin of the lateral nail-folds before the pledget can be introduced. Strips of adhesive diachylon-plaster should then be wound tightly round the phalanx, and a rubber-cot put over the plaster. Much benefit may be obtained by touching any bleeding points or granulations with a silver-nitrate pencil. In twenty-four hours the plaster dressing should be removed, the feet bathed in boric-acid lotion, and a new dressing applied. By this treatment the patient is gradually enabled to wear boots again and to walk about, and the possibilities of complete recovery are considerable. Another method of treatment which is sometimes useful is to moisten the nail with warmed liquor potassæ (40 per cent.), dabbed on with the frayed-end of a piece of cane, and when the nail is softened by this means, to scrape it down with a piece of glass till it is as thin as paper, after which its ingrowing edges may be easily lifted up and cut short with scissors. In the severer forms, namely, the claw- and ram's horn-nails, the above treatment is useless, and complete extirpation should be resorted to. The nail can be removed by cutting-pliers or a fine saw, after which the skin should be stitched over the nail-bed, since in these cases the nail-matrix is as a rule irretrievably damaged, and incapable of re-forming a healthy nail.

B. Atrophies.—Complete or partial atrophy of the nail may be a congenital or an acquired condition. Congenital absence of one or more nails (anonychia) is found in association with other mal-developments of the body. True atrophies of the nail, however, are invariably acquired. An idio-

pathic atrophy of the nails, associated with defluvium capillorum or falling out of the hair, has resulted from severe mental shock (Heller).

For a complete loss of the nail to take place a solution of the continuity between the nail-plate and the nail-matrix is essential, and pathological conditions affecting the nail-bed alone do not, as a rule, produce this solution, as the nail-bed is not in organic connection with the nail-plate, but is only mechanically united to it by the fitting together of the longitudinal ridges on the under surface of the nail-plate and the corresponding grooves on the nail-bed. The more common causes of atrophy of the nail admit of grouping under the following headings:—

ÆTIOLOGY AND PATHOLOGY. — 1. *Trauma.* Severe injuries such as bruises, crushes or blows on the nail, by causing a sudden rupture of the blood-vessels underlying the nail-matrix, and an effusion of blood in the posterior nail-fold, frequently cause a disintegration of the nail-matrix and a shedding of the nail. In these circumstances a new nail usually grows. If the injury is less severe only a temporary arrest in the nail-growth is produced and the nail becomes thin and friable, and presents small ecchymoses in its substance.

2. *Nervous Diseases.*—In cerebral paralysis, tabes dorsalis, syringomyelia, leprosy, division of nerves, and other allied conditions, from the vaso-motor disturbance due to the nerve-lesion, a bleeding may occur about the posterior nail-fold, and atrophic nails may result. In cerebral lesions the great toes are the parts most usually affected. The nails generally grow again if they are shed, unless the shedding results from the division of a large nerve such as the median, when the prognosis is unfavourable.

3. *Blood-Stasis.*—In cyanotic states of the extremities due to cardiac lesions, venous congestions from emphysema, vaso-motor irregularities as in frostbite and Raynaud's disease, atrophic changes in the nails, especially in those of the fingers, are frequently observed. The nails are generally only partially affected and become grey, opaque, lustreless, thin and friable.

4. *Purulent Affections.*—A purulent condition of the soft parts about the nail may cause atrophy and shedding (purulent perionychia). Such an occurrence is familiarly seen in whitlow, but it may occur in tuberculosis, syphilis, and leprosy. As a rule the nail grows again, but in a few rare instances a condition has been set up in which it is no sooner re-formed than it is again undermined and shed (onychitis maligna).

5. *Febrile Atrophy.*—During any acute fever a temporary cessation of growth at the nail-matrix may be noted. In convalescence, however, the nails grow rapidly, but the newly formed nail is peculiarly thin from the narrowing of the posterior nail-fold by the pressure of the turgescient vessels, which are so frequently observed in the extremities before the circulation regains its proper tone.

6. *Scarring Conditions.*—Variola, pustular syphilides, and gummata affecting the nail-matrix or the nail-bed may cause a partial destruction of the matrix, and a loss of the nail, and the subsequent scarring may render the impaired matrix incapable of producing a new one.

7. *Wasting Conditions.*—In chronic tuberculosis, Bright's disease, and diabetes mellitus, a malnutrition of the nail-matrix may take place, and the nails

in consequence may become discoloured, soft, brittle, and tend to crumble.

8. *Cutaneous Affections.*—The nails may be shed in dermatitis exfoliativa, pemphigus, and alopecia areata, and they are frequently partially atrophied in psoriasis, lichen planus, pityriasis rubra pilaris, and ichthyosis.

9. *Intoxications.*—Arsenical, lead- and silver-poisoning may arrest the growth of the nails. Workers in chemical works, who have to put their fingers into acids and alkalis, and bakers or grocers from constantly handling sugar, may suffer from a brittle, opaque state of the nails, similar to that presented by several of the chronic cutaneous affections. In the general intoxications the diseased condition of the nails is caused by an inhibition of the nail-formation at the matrix.

C. Dystrophies.—When the function of the nail-matrix is interfered with, the nails frequently become altered in their texture and colour. They lose their shiny appearance, become dull, brittle, and fissured, and often present whitish opaque specks, whitish striæ, punctiform depressions, or grooves. Together with these degenerations in the nail itself the horny layer of the nail-bed is apt to become thickened in front, causing the nail to be raised up towards its free margin, and sometimes giving rise to a spoon-shaped deformity. At other times the nail-substance formed by the imperfectly acting nail-matrix is peculiarly soft, since the actual cells composing it are swollen and only partially cornified, and the appearance to the naked eye of a bluish translucent wedge usually occupying the lunule-region of the nail is produced. These swollen cells tend to dry and shrivel, air collects between them, and the wedge gradually becomes white, opaque and depressed. When individual papillæ of the matrix are affected whitish specks and punctiform depressions are formed; but when the growth at the matrix is interfered with in its whole extent chalky transverse bands and grooves make their appearance. Similar specks and depressions may also be the result of traumatism from attempts to push back the semilunar fold on the posterior aspect of the nail with a sharp instrument. Dystrophies, such as have been described, are often associated with chronic cutaneous affections, but they occur also in the course of both acute and chronic general illnesses, and lines or furrows may recur with, and serve to mark, each successive attack of an illness.

TREATMENT.—Atrophies and dystrophies of the nails must be treated on purely general principles. Local applications, unless where they are specially indicated by the presence of some purulent affection of the soft parts, are of little value. General treatment, suited to the peculiarities of each case, is of the utmost service. Venous stasis about the extremities should be relieved by improving the general circulation. Many of the apparently hopeless nail-atrophies steadily improve under the influence of tonics, good food and change of climate. In all diseased conditions of the nails careful attention to their culture and absolute cleanliness cannot be too much emphasised. Atrophies due to specific causes must be treated accordingly. The prognosis in the case of atrophies resulting from tuberculosis or leprosy is not so favourable as it is in syphilis.

D. Affections of the nails associated with certain cutaneous diseases.—In most of the chronic dermatoses the nails may become affected at some period or other in the course of the

disease, but it will only be necessary to refer here to psoriasis, eczema, and syphilis, as it is in these diseases that an implication of the nails is most liable to take place.

1. *Psoriasis*.—When the nails are affected in psoriasis the nail-bed is as a rule the chief seat of the disturbance, and the nail becomes implicated secondarily. Small psoriatic spots or papules on the nail-bed cause the latter to become inflamed and swollen, and produce on its surface a heaping-up of partially cornified epidermis, which raises up the nail so that a quill can sometimes be passed under it as far back as the matrix. The nail-plate becomes dry, of a dirty-yellowish colour, and dotted over with opaque specks or punctiform depressions corresponding with underlying papules, or it presents chalky striae or irregular furrows. An implication of the nails is said to occur in about 9 per cent. of cases of psoriasis. This type of diseased nail is occasionally observed in the absence of psoriasis of other parts of the skin, and such cases have been diagnosed as psoriasis of the nails; but as marked variations from the above type are the rule rather than the exception, and as a similar condition of the nails is sometimes present in association with other chronic dermatoses, the diagnosis of psoriasis from the appearance of the nails alone is liable to be fallacious.

2. *Eczema*.—In association with eczema it is the nail itself which is the part most severely affected, for while there is also a heaping up of horny material between the nail and the nail-bed, as in psoriasis, the most pronounced disturbance consists of a roughened and indented condition of the nail and a peculiar worm-eaten appearance of its surface. In moist eczemas there is frequently a sero-purulent perionychia about the nail-fold, and the nail becomes soft, yellow, and opaque. As in psoriasis, the typical appearances of the nails in eczema are so frequently modified that it is doubtful if the description or diagnosis of a specific eczema of the nails is warranted.

3. *Syphilis*.—In both congenital and acquired syphilis the nails may be affected. In congenital syphilis bullae occurring about the nail-bed and matrix may cause a partial destruction or total loss of the nail. In acquired syphilis the nail-bed may be the seat of a primary sore, of papules, pustules, or even gummata, in which conditions the nail itself is always more or less destroyed; but there is no typical manifestation in the nail constantly associated with syphilis.

TREATMENT.—General treatment is of great value in the foregoing diseased states of the nails, and should be carried out on ordinary lines, for since errors in metabolism and want of exercise and fresh air are all potent factors in the production and prolongation of many forms of chronic dermatoses, so are they equally important in keeping up these diseased conditions of the nails. Arsenic has been strongly advocated in nail-affections associated with psoriasis, while those connected with syphilis are amenable to antisyphilitic remedies. Locally it is always an advantage to soften and thin the nails before any application is made. This can be efficiently done by putting the affected digits into rubber-cots containing soft soap for about two hours, and then rubbing the softened nails down with pumice-stone. In eczematous conditions after the nails have been thinned they may be dressed with a paste containing oxide of zinc and salicylic acid, or be painted instead with liquor carbonis

detergens, or some other tar-preparation. Where psoriasis is present elsewhere the following ointment has proved of benefit to the affected nails: Chrysarobin 4 parts, ichthylol 4 parts, salicylic acid 2 parts, and vaseline 100 parts, and this is best applied on pieces of lint covered by a rubber-cot.

E. *Parasitic Diseases of the Nails* (Onychomycosis).—The nail may be attacked by the fungi of ringworm and favus. Occasionally the nail-bed near the free margin of the nail may be the seat of pediculi or scabies, and subungual supuration may result from their presence.

1. *Ringworm of the Nails*.—There is no pathognomonic group of appearances which can be said to represent either ringworm or favus of the nails. As a rule in ringworm the nail is infected first at its free margin. It becomes opaque, and of a dirty yellow or brownish colour. The surface is peculiarly rough, and irregular striae make their appearance on it; the nail becomes friable and is apt to split and even to fall off. The nail-bed is a frequent harbour for the ringworm fungus. If the fungus be confined to the nail-bed the latter becomes thick and spongy, and the nail is raised up, but if the fungus spread back to the matrix an inflammation is set up, which almost invariably ends in the shedding of the nail. When the matrix is not affected the fungus may persist in the nail and the nail-bed for an almost unlimited period. Sometimes in old cases instead of the nail being raised up it becomes unusually thin, indented, and adherent to the nail-bed. This affection of the nails usually occurs with ringworm elsewhere. It is generally met with in the finger-nails, and is more common in adults than in children. Ringworm of the nail, however, is a comparatively rare condition, considering the large number of individuals who must by scratching have the fungus deposited beneath the free margin of the nail. The type of fungus which attacks the nail is usually the large-spored variety, but the small-spored fungus has been found in one or two instances infecting the nails of children.

2. *Favus*.—The favus-parasite when it takes root in the nail-bed produces a superficial catarrh of that region, causing a spongy accumulation beset with fungus to form between the nail-bed and the nail. The nail itself, when attacked by the fungus, becomes yellowish, thickened, rough and opaque. Scutula of favus may form on the nail-bed, and the raised nails present dead-looking areas corresponding to the scutula, and it may become brittle and disintegrate. The differential diagnosis of these conditions is only possible by a microscopical examination, for which purpose scrapings or cuttings of the nail should be softened in warmed 40-per-cent. liquor potassae for fifteen minutes, when the keratin of the nail will be found to have dissolved, and the fungus may be easily demonstrated.

TREATMENT.—When the nail-matrix becomes inflamed and suppurates the nail is shed, and if the matrix be not irretrievably destroyed, a new nail grows. This fact gives the key to the treatment of the parasitic affections of the nails. The most rapid treatment of these conditions is undoubtedly extirpation, and in many cases it is the most satisfactory method. Fourteen days after the excision the patient can use his fingers again, and a new and healthy nail grows in about six months. Where for some reason a surgical operation is inadvisable a similar result may be brought about in the following manner: equal parts of pyrogallic acid and

olive oil smeared on lint are applied twice daily as a dressing to the affected ungual phalanges; in about fourteen days the nail-bed and matrix have begun to inflame and even to suppurate, and the nail may have beneath it a lake of pus and be slightly movable; the application of a moist dressing in a rubber-cot will usually cause a separation of the nail from the matrix in another fortnight. This method of Pellizari, though it gives good results when carefully supervised, when carelessly employed may be followed by serious consequences, for if the pyrogallic acid occasions a too active inflammation at the matrix, the destruction so produced may be so great as to render the formation of a new nail impossible. On this account a slower and less powerful method may be resorted to, which is accompanied by no such risk. Moisten the nail with warmed 40-per-cent. liquor potassæ, rub it thin with pumice-stone, or scrape it with a piece of glass after it has been softened by the alkali, then apply a moist dressing consisting of iodised vaseline (iodine, and iodide of potassium, of each 1 part, water and vaseline, of each 100 parts), spread on lint, and cover the dressing with a rubber-cot. This dressing is renewed twice a week, softening and scraping being repeated if necessary, and a cure is generally obtained in several months. Instead of using the iodised vaseline dressing of Sabouraud, a more rapid result may be obtained by employing a 5-per-cent. chrysarobin ointment, or an ointment containing biniodide of mercury, such as the following: Biniodide of mercury 2 parts, castor oil 12 parts, vaseline 100 parts.

NAPLES, in South Italy.—Changeable climate. Mean temperature, winter, 48° F. Cold winds in spring. See CLIMATE, Treatment of Disease by.

NARCOSIS
NARCOTISM } (*ναρκῶς*, I benumb).—A condition of profound insensibility, due to the action of certain drugs introduced from without, or of certain products formed within the body. See CONSCIOUSNESS, Disorders of; NARCOTICS; and URÆMIA.

NARCOTICS (*ναρκῶς*, I benumb). —.SYNON.: Fr. *Narcotiques*; Ger. *Narkotische Mittel*.

DEFINITION.—Remedies which induce loss of consciousness, motion and sensation, or a condition of profound sleep. In large doses they produce complete insensibility and coma.

The phenomena attending narcosis are well illustrated in the progressive effects of opium, the longest known and most widely used member of the class. The cerebral functions are influenced progressively from above downwards. A transient mental excitement is followed by drowsiness and somnolence, ending in deep stupor. The centres for motion and sensation are concurrently depressed, and finally, if the dose is excessive, the important centres of organic life in the medulla—respiration and circulation—are paralysed, and death ensues. A large number of narcotics are useless as remedies for insomnia. Their effect on the various centres is either simultaneous, or the depression of the medulla may be in excess of and precede any marked influence on the consciousness or sensorium (Hydrocyanic Acid, Aconite). In other instances the preliminary stimulation of the intellectual functions, though finally ending in narcosis, may be

disproportionate and delirium ensues (Belladonna, Cannabis Indica). Hence, from a therapeutical point of view, all such aberrant members of the group will be of little use or even dangerous for the production of artificial sleep and the relief of pain; and can only be used in restricted doses for special purposes and under special conditions.

The term 'narcotic' is now often used in a limited sense to include all drugs which produce a temporary suspension of the intellect, of motion and sensation; and hence becomes equivalent to hypnotic or soporific. Many new substances have been introduced of recent years with the object of producing narcosis, and at the same time avoiding as far as possible any excess of preliminary stimulation, or any final depression of the cardiac and respiratory centres. It can hardly be said that we possess at present a narcotic which is at once both absolutely safe and invariably efficient, and great judgment must be exercised in their administration. Hence the indiscriminate use of these drugs by patients themselves, or by unqualified persons, is to be deprecated. Tolerance in most cases is rapidly established, and increasing doses are required to induce sleep, so that finally even large doses may be ineffectual. Many serious cases of accidental poisoning have arisen from their abuse, and the various drug-habits are unfortunately only too well known. See HABITS.

The entire group of drugs having a narcotic or deadening and benumbing effect is naturally divisible into three main classes: (1) general anæsthetics, (2) general nerve sedatives (analgesics and anodynes), and (3) hypnotics or soporifics. A drug which in a full dose would be classed as an anæsthetic or narcotic will in a smaller one play the rôle of a mild hypnotic or nerve sedative.

Hypnotics or Soporifics.—The primary indication in the treatment of sleeplessness must necessarily lie in the removal of the cause. Hence many measures which, strictly speaking, are not narcotic, or even medicinal at all, may indirectly procure tranquillity and comfortable sleep, e.g. warmth, quiet, and the removal of any disturbing influences. Sleep is often promoted by dilating the vessels of other parts of the body than the brain, as, for example, by a warm bath or a full meal. Again, the insomnia of fever may be temporarily relieved by the use of antipyretics, such as quinine, phenacetin, phenazonum, or acetanilidum, but the relief is only temporary, and such drugs must not be employed in a routine fashion. The sleeplessness of exhaustion and feebleness may yield readily to a little nourishment or to a well-timed dose of alcohol. Pain is probably one of the most frequent causes of want of sleep, and if it is removed sleep usually follows. This may be often effected by other means than by internal medication, as, for example, by local surgical procedures, by the application of heat and cold, and by the use of local anodynes. It is generally best, for the reasons already stated, to exhaust all local, non-medicinal, domestic and indirect measures for the relief of sleeplessness before proceeding to the use of hypnotic drugs.

A convenient clinical classification of medicines employed for the artificial production of sleep is into (1) those which are used when pain is the chief cause of the insomnia, and (2) those which are indicated when restlessness, mental excitement, overwork and similar conditions are the predominant factors.

In the first group Opium and Morphine are the most efficient narcotics. The principal drawbacks to opium are (1) the disturbance of digestion and of the secretions and excretions attending its use, and (2) the fact that increasing doses are needed to overcome the toleration which is rapidly developed. As a hypnotic morphine is better given hypodermically than by the mouth, as its narcotic action is more quickly induced, its dose is more accurately regulated, and its effect on secretion is less marked. For the last-named purpose a minute dose of atropine is sometimes combined with the morphine. It will be noted that the official hypodermic injection of morphine was made considerably weaker in the last revision of the 'British Pharmacopœia' (1898), and is now a five-per-cent. solution of the tartrate of morphine.

In the second group of hypnotics, suitable for cases where pain is not the essential cause of the insomnia, many useful drugs are included; and of these, chloral hydrate, the bromides, chloralamide, sulphonal and trional are perhaps the most satisfactory.

As a hypnotic, *Chloral Hydrate* acts more quickly than morphine, even when given subcutaneously. It often succeeds when morphine has failed, and is rarely followed by any unpleasant effects on digestion. It does not, however, relieve pain, and may cause great cardiac and respiratory depression. It is useful in cases of mental excitement and mania, but it must be always borne in mind that a chloral-habit, like a morphine-habit, is easily established. *Butyl-Chloral Hydrate* has a somewhat similar action to chloral hydrate, but is less rapid, less powerful, and less certain. It has, however, the special advantage of relieving trigeminal neuralgia in some instances. The *Bromides* are peculiarly well fitted to soothe the brain when rendered irritable by overwork, but are very uncertain in their action as hypnotics. Bromide of potassium is often usefully combined with chloral hydrate. *Chloral-amide* is a fairly certain and safe hypnotic. It is valuable in the insomnia of cardiac disease and in some cases of nervous excitement. Its effects, however, are often very variable, but it has the advantage of not leading to any 'habit.' *Sulphonal* and its congeners *trional* and *tetronal* do not as a rule derange digestion, nor seriously depress the circulation and respiration, and may therefore be safely ordered in diseases of the heart and lungs, where the more powerful hypnotics such as morphine and chloral hydrate are contra-indicated. Their action is, however, somewhat slow and uncertain, and the use of sulphonal may be followed by prolonged drowsiness, giddiness and eruptions. See SULPHONALISM.

FREDERICK WILLCOCKS.

NASAL CALCULI.—See CONCRETIONS.

NASHA FEVER.—A term applied in India to an inflammation of the mucous membrane of the septum nasi, accompanied by fever, and lasting about a week. It is uncertain whether the condition should be regarded as a definite disease.

NASO-PHARYNX.—See NOSE, Diseases of.

NATAL, in South Africa.—Warm, but healthy climate, with hot, wet summers, and dry, clear winters. High winds from S.E. and N.W. Soil, sandstone and granite. See CLIMATE, Treatment of Disease by.

NAUHEIM, in Germany.—Gaseous thermal salt waters. See MINERAL WATERS.

NAUSEA (*ναῦς*, a ship).—An inclination to vomit. See SEA-SICKNESS; and VOMITING.

NAUSEANTS (*ναῦς*, a ship).—DEFINITION. Agents which produce the feeling of nausea.

ENUMERATION.—The principal nauseants are Warm Water, Tartar Emetic, Ipecacuanha, Tobacco, Squill, and Apomorphine.

ACTION.—These substances produce irritation of the stomach, loss of appetite, general malaise, enfeebled circulation, muscular weakness, and frequently also salivation and sweating.

USES.—Nauseants have been employed to diminish appetite, in the hope of causing absorption of fatty accumulations or of pathological deposits. They are also used in producing relaxation of involuntary muscular fibre, and thus accelerating the passage of calculi through the bile-duct or the ureters; and occasionally they have been employed to relax rigidity of the os uteri in labour. They are sometimes given to excite sweating. See DIAPHORETICS; and EMETICS.

LAUDER BRUNTON.

NEAR-SIGHTEDNESS.—See MYOPIA; and VISION, Disorders of.

NECROBIOSIS (*νεκρός*, a dead body; and *βίος*, life).—Molecular death of a tissue without loss of continuity, especially seen in the various forms of atrophy and degeneration. See ATROPHY; and DEGENERATION.

NECROPSY (*νεκρός*, a dead body; and *ψις*, a view).—SYNON.: Autopsy; Fr. *Nécropsie*; Ger. *Leichenschau*.

DEFINITION.—The inspection and examination of the body after death.

Method.—The external surface of the body should first be carefully examined, note being taken of the presence or absence of wasting, the degree of rigor mortis, changes in colour, partial or general, œdema, marks of injury, and other points which may suggest themselves. In medico-legal cases it is of importance to measure, and accurately record on the spot, the precise position of external wounds or marks of injury.

When the external examination is complete the body is opened. The following general principles should be observed: (1) Examine first the viscera *in situ*, and ascertain whether there is any departure from their natural position and relations. When this has been done, and not before, the individual organs may be removed from their connections and subjected to closer examination. (2) Examine all the viscera and accessible organs, i.e. let the necropsy be thorough and complete. Do not neglect the lymphatic glands, the thyroid and suprarenal bodies, or bone-marrow. Many an erroneous conclusion has been drawn as to the cause of death by a partial examination. It happens not rarely that relatives will only consent to a partial examination of the body. Where this is the case it is still possible to examine all the important thoracic and abdominal viscera through a comparatively small external incision, without in any way hurting the feelings of the relatives, since the restriction may be held to refer to external disfigurement only. (3) In all cases it is important so to conduct the

examination as to give rise to as little disfigurement as possible; attention to the rules given below will render this easy. At the conclusion of the examination the organs should be replaced, all incisions closed by a neat continuous suture, and the surface of the body cleansed. When it is necessary to conduct the necropsy in a private house, care must be taken to avoid needless soiling of linen or furniture. (4) It often happens that a bacteriological examination is required. If the individual conducting the examination is not himself competent to undertake this, he should secure the presence of a bacteriologist at the time the body is opened. Blood, for instance, should always be collected from the unopened heart *in situ*. For ordinary histological purposes portions of suspected organs should be placed as soon as possible in Müller's fluid or some suitable hardening agent.

The order in which the different regions of the body are examined varies with the practice of the individual making the examination. Some prefer to commence with the central nervous system, others leave this till last. In all cases the thorax should be examined before the abdomen, because the pressure-relations of the thorax are much altered by removal of the abdominal viscera. In this article we commence with the central nervous system, but it must be understood that in any given case there may exist reasons for beginning in some special region. Where the spinal cord has to be examined it is usually desirable to complete this before exposing the brain.

Head.—To open the head, make an incision down to the bone, above the vertex from the base of one mastoid process to the other, and reflect the scalp backwards and forwards; then divide the bone all round with the saw, beginning in front a little above the level of the superciliary ridge. The posterior half of this section should make an angle with the anterior half by being brought over the occipital bone, a little behind the apex of the lambdoidal suture. By this means the skull-cap will, when replaced, rest firmly in its position without slipping back, and so causing disfigurement of the forehead. In cases of fracture of the skull the section should be completed with the saw, care being taken not to wound the dura mater. Under other circumstances the inner table may be conveniently divided with a chisel and mallet. The skull-cap must now be forcibly dragged off; if very adherent to the dura mater, a long flexible spatula may be introduced between them, and separation thus effected.

In young subjects before the sutures and fontanelles are united, it is better to remove the dura mater and skull-cap together, by dividing the former with blunt-pointed scissors in a line with the section through the bone, and then cutting through the falx at its anterior and posterior attachments.

The longitudinal sinus may now be opened and examined. The dura mater should next be divided on each side with blunt-pointed scissors, on the level of the section through the bone, and the two lateral flaps turned up; then the falx should be cut near its anterior attachment, and the whole membrane drawn backwards off the hemispheres. The brain must now be removed; a long narrow scalpel being used to cut through the nerves and vessels, while the tentorium is most safely divided with blunt-pointed scissors. The spinal cord should be cut across as low as possible. Any fluid present at the base of the skull should be drawn off with a syringe and measured.

Brain.—The pia mater and surface of the brain should now be examined; for this purpose it is rarely needful to strip the pia mater off the brain, though this can be done when required. The brain should be placed on its base, and, if very soft, supported by a towel wrapped round it. A horizontal incision should be carried through each cerebral hemisphere, on a level with the upper surface of the corpus callosum, from within outwards, not quite reaching the surface, so as to leave the hemispheres still attached to the rest of the brain. These should be turned aside, and numerous vertical incisions made in the upturned surface. Each lateral ventricle should then be opened by a vertical incision through its roof, and any fluid contents withdrawn by a syringe. The fornix should now be divided in front, and with the septum and corpus callosum turned backwards. The velum interpositum and choroid plexus being reflected in a similar manner, numerous longitudinal incisions should be made in the corpora striata and thalami optici, and in the corpora quadrigemina. An incision should now be made through the superior vermiciform process of the cerebellum, so as to lay open the fourth ventricle. The cerebellum may be examined by making parallel incisions on each side through its lobes, not quite detaching the sections. The brain may now be folded together again, and the under surface turned up and examined. Incisions should be made into the under surface of the cerebral lobes, and into the crura and pons; and the medulla divided transversely at different levels. Softened portions should be tested with a stream of water; and parts reserved for microscopical examination at once placed in a hardening solution, such as chromic acid (1 per cent.).

In some cases, however, where it is requisite to determine with the greatest attainable accuracy the precise limits of a cerebral lesion, it is desirable to harden the entire brain before opening it. This is best done by placing it, suitably supported by a bed of tow or cotton-wool to prevent deformation, in a 10-per-cent. solution of formalin. In a few weeks it may be examined by the sections above described, with much more satisfactory result than in the fresh condition.

Base of Skull, Orbit, and Internal Ear.—The base of the skull and its sinuses may now be examined. In cases of fracture, the dura mater should be carefully stripped off, so as to expose the surface of the bone. The contents of the orbit may be examined by removing its roof. The tympanum can be opened by cutting through with a chisel the plate of bone forming its roof. This is situated on the anterior surface of the petrous bone, just in front of the eminence of the superior semicircular canal. To examine the internal ear the petrous bone must be removed. This is best done by two converging incisions made with a saw, and then separating the apex of the wedge from the sphenoid and occipital bones with the chisel.

Spinal Cord.—To examine the spinal cord the body must be turned on its face, with the head hanging over the table, and a block placed under the chest. An incision must be made over the vertebral spines from the top of the sacrum to the occiput, and the vertebral arches laid bare. These are best divided with the rachitome, a double semicircular saw, in the absence of which a short common saw may be used, or a chisel and mallet or bone-forceps. The cord should be removed in its tube of

dura mater, the latter being held by the forceps, and care taken not to bend the cord abruptly. The dura mater should then be slit open with blunt-pointed scissors along its anterior and posterior surfaces, and the cord examined, with as little handling as possible, by means of transverse sections made with a sharp scalpel. For microscopical examination the cord may be placed in spirit for about twenty-four hours; and then, after removal of its membranes, cut into lengths, and transferred to a 1-per-cent. solution of chromic acid. A still better method of hardening the cord for microscopic purposes is to hang it up in a 10-per-cent. solution of formalin. In this it may be kept till it is cut, or it may be transferred after a week or two to Müller's fluid.

A method of opening the spinal canal from the front, preferable in many respects to the above, is practised at Vienna and many places on the Continent. The instruments used are a strong knife-shaped chisel, with a cutting beak, and a mallet. After the removal of the thoracic and abdominal viscera, the beak of the chisel is introduced into the lowest intervertebral foramen, and by successive blows of the mallet the pedicles of the vertebrae are cut through on each side and the canal exposed by removing the bodies. In this way great disfigurement of the body and soiling of the table and linen are avoided, and the spinal ganglia are more easily examined.

Thorax and Abdomen.—The thorax and abdomen should now be examined. It is better to lay the abdominal cavity fully open before removing the sternum. In cutting through the first rib, and disarticulating the clavicle, care should be taken not to wound the innominate vein. By using cutting pliers, which should be directed so as to cut obliquely through the rib into the articulation, all danger is avoided.

If much ascites is present, the belly should be tapped before laying open the peritoneal cavity. So, if either pleura be full of fluid, which will be shown by its pouring out when the cartilages of the ribs are cut through, sufficient should be drawn off with a syringe to prevent any overflow when the sternum is removed.

The lungs should now be drawn out of the chest, adhesions separated, and their posterior surfaces examined. The contents of the mediastinum should next be inspected, and the pericardium opened. If the case be one of thoracic aneurysm, mediastinal tumour, or malformation of the heart or great vessels, the heart and lungs should be removed together. Otherwise, the heart may be first removed and examined.

Heart.—The auricles should be laid freely open with a pair of scissors, by an incision joining the mouths of the great veins and carried to the extremity of the auricular appendage. The competency of the valves may then be tested. All clots must first be removed, the heart held in an upright position, and water poured into the aorta and pulmonary artery successively, the semilunar valves being held back with the handle of a scalpel to allow the ventricle to become filled; on looking into the auricles the competency of the auriculo-ventricular valves may be estimated. To test the semilunar valves an opening must be made into each ventricle; the pulmonary artery and aorta cut sufficiently close to enable the valves to be clearly seen; and then water poured into these two vessels successively,

and the valves looked at from above. The right ventricle may now be opened. The left forefinger should be introduced through the pulmonary artery, and the anterior wall of the ventricle divided with blunt-pointed scissors into the artery, the point of the scissors being guided by the left forefinger to the junction of the valves. The pulmonary artery and aorta should then be separated as much as possible, and the left ventricle opened in a similar manner along its anterior wall, the left forefinger as before guiding the scissors to the point of junction of the semilunar valves. The incision must be carried close to the ventricular septum, and the septum between the aorta and pulmonary artery, but without cutting the latter. The most accurate way of measuring the capacity of the orifices is to pass through them graduated balls fixed on rods, in default of which the fingers may be used. Before concluding the examination of the heart, the condition of the coronary arteries, and of their origins from the aorta, should be investigated. They often share in the atheromatous changes which have occurred in the aorta, and in some cases sudden death seems to be attributable to their blockage.

Lungs.—To remove the lungs, the trachea must be cut across at the root of the neck, and well drawn forwards by inserting the middle finger into the lower end, and the other fingers on each side behind the bifurcation, care being taken not to cut the œsophagus.

To examine the lungs, if the lobes are firmly bound together by adhesions, it is best to carry an incision in a vertical transverse plane from the outer border inwards towards the root. Further incisions may be made parallel to the first, in front and behind it. Cuts made in this direction lie in the plane of the large vessels and air-tubes.

If the lobes are separate, the incisions should be so managed as to give the largest possible sectional area. The lower lobe, as before, should be cut from without inwards, but it is usually more convenient to commence the incision for the upper lobe by inserting the knife in the septum between it and the lower, and carrying the incision midway between its root and its external surface. The vessels and bronchi should be slit up by probe-pointed scissors. The condition of the lymphatic glands at the root of the lung should always be observed and noted.

Larynx and Pharynx.—To remove the larynx and pharynx, the incision in the neck must be carried up to the chin; the floor of the mouth opened from below; the left forefinger introduced, and used to depress the tongue; a long narrow scalpel introduced above the finger, and carried along each side of the ramus of the jaw; the tongue then drawn down under the chin; and the soft palate and pharynx divided transversely. The pharynx and larynx should then be opened along their posterior walls.

The œsophagus, which should have been left undamaged in the removal of the other thoracic viscera, must also be opened and examined. There are many who make a routine practice of removing *en masse* the tongue, fauces, larynx, pharynx, and thoracic viscera, and this proceeding has much to recommend it, as it allows of a more complete examination of the relations of the different parts. After removal of the sternum and study of the thoracic viscera *in situ*, the tongue and fauces are dissected out, and the parts then removed from the vertebral column from above downwards, the œsophagus and aorta being divided at the diaphragm.

The pharynx and œsophagus are then laid open from behind. The larynx, trachea and bronchi are next similarly treated, as is the descending thoracic aorta. The heart and lungs can finally be studied in detail.

Intestines.—In examining the abdomen it is most convenient to begin with the intestines. The large intestine should be divided between two ligatures below the sigmoid flexure, and drawn out, cutting the mesentery close to the bowel. This process should be continued till the duodenum is reached, when it may be again tied and cut. The intestine should be opened along the line of attachment of the mesentery. Before the bowel is opened, it is convenient to wash out its contents. This may be done by tying the upper end to a tap and turning on the water for a few minutes. The mesentery and its lymphatic glands must receive due attention, especially as to the presence of tubercular lesions in the latter. The rectum must finally be examined as far as the anus.

Spleen.—The spleen may next be examined. It should be drawn forwards out of the abdomen, and the gastro-splenic omentum cut through. It should then be placed on its hilum and laid open by a vertical incision.

Stomach.—The stomach should next be removed. A double ligature should be placed round the duodenum about two inches below the pylorus, and another one round the lower end of the œsophagus, and these tubes cut through, so as to remove the stomach without the escape of its contents. If required for chemical analysis, the contents should be emptied into a glass vessel, by removing the œsophageal ligature.

The usual practice is to lay open the stomach along its lesser curvature, from the œsophagus to the duodenum; but in many cases it is better to carry the incision along the greater curvature, for, as ulcers and cancers are more frequently situated near the lesser curvature, this incision is more likely to avoid cutting through them.

Unless required for chemical analysis, the mucous membrane may be washed by a gentle stream of water and then examined.

Pancreas.—After the removal of the stomach the pancreas may be conveniently examined. Before separating it from the duodenum the condition of its duct should be ascertained.

Liver.—In all cases of jaundice the liver and duodenum should be removed together, so as to obtain the bile-duct intact. In removing the liver care should be taken not to injure the right suprarenal capsule, which is in close contact and often adherent. In testing the perviousness of the bile-ducts it is better not to squeeze the gall-bladder, as this will often overcome an obstruction, but to open the duct with scissors, and observe the colour of the lining membrane below an obstruction. This will be found unstained by bile, if the obstruction be complete.

To examine the interior of the liver a number of vertical incisions should be made through the organ extending nearly to the posterior border. The thickness of the capsule, appearance of the surface, and condition of the vessels and ducts on section should be carefully noted. The gall-bladder should also be opened up, and its contents and inner surface observed.

Suprarenal Capsules.—The suprarenal capsules should be removed united with the semilunar ganglia and solar plexus.

Genito-urinary Organs.—In all cases of urinary obstruction the kidneys, ureters, and bladder should be removed in connection. The pelvic organs may be removed *en masse* by carrying a large knife all round the pelvic walls, and drawing the viscera upwards and backwards. As much of the urethra as may be required can be pulled back under the pubic arch. The urethra and bladder should be opened with scissors along their upper wall.

The uterus may be examined by introducing one blade of a pair of probe-pointed scissors through the os; making an incision through the anterior or posterior wall to the fundus; and carrying this on each side to the entrance of the Fallopian tubes, which will be studied along with the ovaries.

The kidney may be bisected by an incision through it from the convex border to the hilum; the capsule should then be stripped off, its thickness and degree of adhesion being noticed; and the state of the surface of the kidney, both external and on section, carefully observed.

The *thyroid gland* and the *thymus* or its remains will have been examined with the thoracic viscera. The *testes* may readily be pulled up from the scrotum and incised. In certain blood-diseases it is of importance to ascertain the condition of the *bone-marrow*. The sternum and the ribs offer special facilities for this, but it is sometimes desirable to examine one of the long bones. A slight prolongation of the abdominal incision will easily enable a section of the upper end of the femur to be made with a saw, or, if preferred a tibia or other long bone may be removed and sawn down. The knees and great-toe joints should be examined for gouty deposits.

There are certain rough chemical reactions which are frequently required in the *post-mortem* room. The chief of these are the iodine-test for amyloid disease, and the iron-reaction in pernicious anemia. Both tests are simple. In the first a section of the suspected organ is made with a clean knife; a weak solution of iodine is then poured over the surface, and, after a minute or two, washed away with a current of water; any amyloid material present stains a dark mahogany-brown colour, in striking contrast to the pale yellow of the other tissues. The iron-reaction is brought out on a similar fresh section of the liver or other organ by pouring over it successively a solution of ferrocyanide of potassium, and then dilute hydrochloric acid. Prussian blue is formed if any notable amount of iron be present in the tissue.

W. CAYLEY.

F. W. ANDREWES.

NECROSIS (*νεκρός*, a dead body).—The absolute death of a circumscribed portion of any tissue: clinically the phrase is usually associated with death of bone. See BONE, Diseases of.

NEGRO-LETHARGY.—SYNON.: The Sleeping Sickness of the Congo; Fr. *Maladie du Sommeil*; *Nélaiane*; *Didane*.

DEFINITION.—An endemic disease of the West Coast of Africa, affecting the central nervous system; characterised by slowly developed and increasing muscular debility, torpor and somnolence; and terminating, after a variable period of months or years, in death.

GEOGRAPHICAL DISTRIBUTION.—This disease is endemic, and liable to epidemic outbursts, in Western Africa between Senegambia in the north,

and S. Paul de Loanda in the south. How far it extends into the interior of the country is not known. It occurs as high up the Congo as Stanley Pool, and is said to be gradually spreading to the upper reaches of this river and its affluents. A case has been reported as high up the Niger as Timbuctoo. It is said to be unknown on the lower part of the Niger (Crosse), at the mouth of the Congo, at Sierra Leone, and at other places in the endemic area. It is just possible that it occurs among the aboriginal Buck Indians in British Guiana, South America. Formerly it was common as an imported disease among the negroes in the West India Islands; since the abolition of the slave-trade it is unknown there. Cases have occurred in England, also in West Coast Negroes. A striking peculiarity about the disease is that it may remain latent for a very long time, and not declare itself until years after the endemic area has been quitted. According to the natives, the liability continues for seven years.

ÆTIOLOGY.—Sleeping sickness has been attributed, on very insufficient grounds, to a variety of causes, none of which, however, on investigation, can be found to account for it. There are some grounds, however, for suspecting that it is in some way connected with the *Filaria perstans*. Certain it is that this parasite has been found in the blood in a large proportion of the cases in which it has been properly searched for. Such a cause would explain the peculiarities of the endemicity of the disease, and also the singular liability to its development years after the victim has left the endemic area. The recent discovery of this filaria among the Buck Indians of British Guiana, and the possibility, as reported by Ozzard, that sleeping sickness occurs among them, seem to indicate a causal relationship.

ANATOMICAL CHARACTERS.—Manifestly sleeping sickness is a brain-disease, and in two cases of which the organs were recently examined under the most favourable conditions, Mott showed that the essential lesion is an extensive meningo-encephalitis, sections of the brain showing extensive and possibly general infiltration of the sheaths of the blood-vessels with leucocytes. No gross lesion was discovered in either case.

SYMPTOMS.—Negro-lethargy attacks both sexes and all ages; it is stated to have a predilection for the young, vigorous, and intelligent of about eighteen or twenty. It commences insidiously with lassitude, muscular and intellectual debility, often moroseness, and an irresistible tendency to fall asleep at unwonted times and even while at work. Dull headache is sometimes complained of, but not always. A tottering and unsteady gait, as if from weakness, is a frequent and early symptom, as is also a peculiar and pathognomonic *facies*: the upper eyelids droop as if weighed down by sleep, the eyes are lustreless and the face puffy, and the expression is sad or taciturn. The memory becomes weak and the senses dull. Little by little, sometimes interrupted by deceptive periods of arrest or improvement, the state of torpor becomes intensified, so that after a time sleep is nearly continuous; or, if not asleep, the patient will lie with closed eyes in an apathetic condition from which he can be roused with difficulty. He may generally be got to reply to questions, but he is unable to sustain a conversation, and speedily relapses into his habitual state of lethargy. At this stage, were he not

roused to take food he would starve to death; even after being roused up, so great is the somnolence that he may fall asleep again in the act of conveying food to his mouth or during mastication. There may be some evening rise of temperature; but for the most part the skin is abnormally cold, the patient evidently feeling chilly and liking to lie asleep in the hot sun. Examination fails to detect any disease of the thoracic or abdominal viscera; the fundus oculi is healthy; and the superficial and deep reflexes are preserved. Although appetite and digestion generally continue unimpaired, towards the end of the disease the body wastes; the sphincters may fail to act; and extensive bed-sores may form. Limited areas of skin may become anæsthetic. Muscular tremor is frequently noted; and as the disease advances, localised muscular spasms or more general convulsions may supervene. Death may occur during one of these convulsions, or it may be brought about by simple inanition or by some intercurrent disease. A certain proportion of the cases exhibit maniacal symptoms at an early stage; these may subside, or recur, or persist for a variable period before the development of the characteristic somnolence. Enlargement of the cervical glands, and of the salivary glands with a degree of salivation, and an itching papular or papulo-vesicular eruption on the chest and limbs are said to be almost invariably observed.

The symptoms described are not all present in every case, and the individual features vary much in different instances, in degree and combination and rate of progress. Progress may be rapid or slow, so that the duration of sleeping sickness is variously stated at from four or five months to as many years. Cases are on record in which recovery seemed to take place, to be followed, however, almost invariably, sooner or later, by relapse and death. It is doubtful, indeed, if permanent recovery ever really does take place. The negro smitten with sleeping sickness considers himself and is looked on by his companions as doomed.

In the districts in which this disease occurs the distribution of the cases appears to be most capricious. A dozen negroes may be sleeping to death in one village, while the neighbouring villages are, and continue to be, entirely exempt or only slightly affected. Similarly, it seems to cling to particular houses and families, and thereby acquires a false appearance of heredity. So terrible are its visitations that whole villages are decimated by it, and entire districts abandoned from the fear of it by their panic-stricken inhabitants.

DIAGNOSIS.—Negro-lethargy has been confounded with beriberi, a disease also endemic on the West Coast; but, if it be borne in mind that the former is a disease of the central, whereas the latter is a disease of the peripheral nervous system, mistake is not likely to be made. See BERIBERI.

TREATMENT.—No treatment has been found to be of any real and lasting service in negro-lethargy, though purging appears to do good temporarily, and arsenic in very large doses has seemed to be followed by improvement, and even arrest. If in the future it should turn out that the *Filaria perstans* is in ætiological relationship to the disease, much may be expected from an intelligent prophylaxis. See FILARIASIS. PATRICK MANSON.

NENNDORF, in Prussia (Hesse).—Cold sulphurous lime-waters.

NEOPLASMS (νέος, new; and πλάσσω, I mould).—A term for new-growths. See TUMOURS.

NEPHRALGIA.—DEFINITION.—The name applied to a variety of renal pain unaccompanied by any ascertained lesion in the kidneys, or by any morbid changes in the urine. Nephralgia is said to be dependent on exhaustion, on exposure to cold, and, according to Grainger Stewart, on the action of malarial, rheumatic, or gouty poisons. The pain is essentially of the same character as that met with in one variety of renal colic. It is felt in the loin and over the anterior surface of the abdomen, but it does not radiate into the groin nor down the thigh. It is usually constant but is liable to exacerbation, especially on exertion; and in this respect also it resembles closely the pain of renal colic, and may be indistinguishable from it if the latter is unaccompanied by the presence of blood or other abnormal constituents in the urine. Most cases of nephralgia occur in neurotic or neurasthenic patients. In many cases where the severity of the nephralgia has led to the diagnosis of renal calculus, nephrotomy and even nephrectomy have been performed, and although no calculus was found, yet a permanent relief of pain followed the operation. It is probable that some cases of so-called nephralgia are really dependent on pre-natural mobility of the kidney causing kinking of the renal vein, and that the distension of the organ so produced has caused the pain. In other cases it is possible that the pain may be dependent on slight anomalies of the ureter causing slight hydro-nephrosis. In both instances the fixation of the organ, produced as a result of the operative interference, may prevent the recurrence of the pain.

DIAGNOSIS.—Nephralgia should not be accepted as a diagnosis until all possible means have been adopted to exclude the presence of calculus, hydro-nephrosis or movable kidney.

PROGNOSIS.—In many cases the discomfort is relatively trivial; in others the severity of the pain is such as to produce a condition of neurasthenia, and this is especially liable to occur if the patient has sought relief by taking morphine or other drugs for the relief of the pain.

TREATMENT.—In mild cases counter-irritation and the support of the organ with a well-fitting pad is all that is required. If the pain produced is very severe an exploratory nephrotomy may not only be justifiable but even advisable.

JOHN ROSE BRADFORD.

NEPHRITIS (νεφρός, the kidney).—A general term for inflammation of the kidney. See BRIGHT'S DISEASE; and KIDNEYS, Diseases of.

NEPHROLITHIASIS (νεφρός; and λίθος, a stone).—The formation of stone in the kidney. See CONCRETIONS; and RENAL CALCULUS.

NEPHROPTOSIS (νεφρός; and πῶσις, falling). Prolapse of the Kidney. See KIDNEY, Malpositions of, p. 835.

NERIS, in France (Allier).—Feebly mineralised, alkaline, saline, thermal waters. See MINERAL WATERS.

NERVES, Diseases and Injuries of.—SYNON.: Fr. *Maladies des Nerfs*; Ger. *Nervenerkrankheiten*.—Nerves, in their origin, course, and distribution, are connected with the several organs and tissues of the body, and are consequently

affected in various ways when such parts are disordered or diseased. But, besides such *secondary* derangements, nerves are subject to many morbid conditions which affect them *primarily*. In the case of certain classes of nerves, connected with special functions, the effects produced by disease are at once so distinct and so important that they require separate consideration. Such, for example, are the glosso-pharyngeal, hypoglossal, olfactory, optic, phrenic, pneumogastric, spinal-accessory, sixth and third cranial nerves, the morbid conditions of which will be found fully discussed under their respective headings. Again, certain forms of congestion or inflammation (whether occurring in the subjects of gout, rheumatism, malaria, plumbism, syphilis, or in other states), when they affect important nerves, cause symptoms of a character so marked, either in their progress or distribution, or by their severity, as to deserve a special designation, and to demand separate description (see INTERCOSTAL NEURALGIA; NEURITIS; SCIATICA; and TIC-DOULOUREUX). In these and in other allied instances the prominent symptoms are referable to functional disturbances of the nerves. In another class of cases similar phenomena originate in interference with the general nutrition, in disease of the nervous centres, or by reflex action; and these phenomena will be found discussed in the articles upon CONVULSIONS, EPILEPSY, and NEURALGIA.

In this place there remain for special consideration the following subjects: (1) the effects of *injuries* of nerves; (2) the most common morbid growths involving nerves, which are generally known as *neuromata*; and (3) the effect of cutting or stretching nerves regarded as a means of *treatment*.

1. Nerves, Injuries of.—Nerves may be divided accidentally either by tearing or cutting, or surgically during an operation, or for the relief of pain or resection of tumours. The nerves most frequently divided accidentally are those of the upper extremity, especially the ulnar, and the median just above the wrist-joint. The injury is very often caused by broken glass.

Sometimes, besides being wholly or partially divided, nerves may be bruised, or have embedded in their substance particles of friable foreign bodies, such as glass or slate. Fractures of the humerus at the upper or lower third are not uncommonly complicated with injury of the musculo-spiral nerve by the sharp edge of one of the fragments; for the nerve passes spirally round and in close contact with the humerus, first on the inner, then on the hinder, and near the elbow at the outer aspect of the bone.

SYMPTOMS.—The symptoms of the division of a nerve are loss of power in the muscles, and of sensation in the skin, supplied by the branches of the injured nerve. The complete or the partial division may be diagnosed by the more or less complete interruption of these functions. It should, however, be remembered that there is often not complete anaesthesia, and that the state of the muscles is more important than is the loss of sensation.

In addition to the paralysis of motion, the *muscles* atrophy with great rapidity, and in many cases shrink so as to cause various deformities. In other cases deformity results from the unbalanced active contraction of the neighbouring healthy muscles. Examined electrically, faradic contractility is found

to be diminished as early as the second day, and completely lost from the third to the sixth. The galvanic contractility remains for from three to twelve weeks, but abnormally strong currents are required to produce contractions in proportion as the muscular tissue disappears. The so-called 'reaction of degeneration' is evident within a week or two of the section, and indicates with certainty that the muscle is for the time separated from its nerve-centre. See ELECTRICITY IN MEDICINE.

The *skin* and its appendages also suffer. At first, on account of the section of the vaso-motor nerves the parts are flushed and hot; but, within a fortnight or three weeks, there is established a spasm of the small arterioles, resulting in diminished blood-supply and coldness of the paralysed parts. In many cases the skin becomes red, shiny, and glossy; and ulcers or whitlows may form painlessly, originating in some cases from injury to an anæsthetic part, in other cases being apparently spontaneous. The *nails* become fibrous and brittle, with ridges and fissures on them, and in some cases are shed. The *hair* breaks off short or else falls out. The *joints* are at first swollen and painful, but later on are liable to become stiff and ankylosed. The *fat* and *subcutaneous tissues* atrophy.

Changes in the divided nerve.—The lower end of the divided nerve undergoes rapid atrophy and degeneration, the myelin being broken up and absorbed and the axis-cylinders quickly destroyed. This degeneration affects simultaneously the whole of the lower end and its branches, but is in all cases succeeded after an interval of some months by imperfect attempts at repair, and the formation of new axis-cylinders from the nuclei of the sheath of Schwann. The proximal end as a whole undergoes no change, except a slow atrophy which ensues after a lapse of years. Its cut extremity, however, soon increases in size, and on it a bulbous swelling forms, which, in a nerve the size of the median, is about half an inch in length by a third of an inch in diameter. This bulb is formed of fibrous tissue and young nerve-fibres. If the cut ends are in apposition, *union* occurs by a growth of nerve-tissue from the nuclei of the sheath; but the process is generally a slow one, and is usually preceded by degeneration of the lower end as already described. If good apposition is not maintained, union either does not occur at all or else it is very imperfect.

TREATMENT.—In the treatment of nerves accidentally divided all foreign bodies are, in the first place, to be carefully removed by means of a thoroughly aseptic sponge or forceps, with as little injury to the nerve-tissue as possible; and the wound, if practicable, is to be treated antiseptically. The limb should afterwards be fixed upon splints in a position which will bring the cut ends of the divided nerve most easily and closely into apposition. Chromicised catgut or kangaroo-tendon sutures should be passed completely through the nerve about a quarter of an inch from the cut surfaces, and tied tightly enough to obtain good apposition, but not so as to crush the nerve-fibres. Two sutures are usually sufficient. If possible, none of the nerve-fibres should be cut away, although a slight trimming off of jagged ends may be advisable. Passive motion of the paralysed muscles should be employed as soon as the wound is united; and afterwards weak galvanism should be applied to the limb, to promote nutrition and stimulate nerve-currents. It is also of much importance to keep the parts suffi-

ciently warm. In most of the cases so treated a good result is ultimately obtained, although it may be delayed as much as one or even two years. Sensation commonly returns before motor power, and voluntary power before electrical excitability.

In cases where a nerve has been for long divided and has not united on account of want of proper treatment by suture, the operation of *secondary suture* should be performed. The limb should be rendered bloodless by an Esmarch's bandage, and the separated ends exposed by a careful dissection. The greater part of the bulb should then be cut cleanly off, and the lower end should be refreshed. Sutures should then be passed as described above. When the ends are too far apart to be brought into apposition a portion of nerve taken from an animal or from a recently amputated limb may be used to connect the separated ends. These operations are sometimes tedious and difficult.

2. Nerves, Tumours of.—SYNON.: Neuro-mata.

The tumours which affect nerve-structure, although no doubt varying in essential character, as they do in other parts of the body, have usually been grouped indiscriminately under the head of Neuro-mata. They may be divided into two classes—(a) *true*; (b) *false*.

A *true* neuroma is one which is composed of nervous tissue, and may contain medullated or non-medullated fibres, and in addition ganglion cells; all such tumours are exceedingly rare.

A *false* neuroma is a tumour situated on a nerve and not itself containing any nerve-elements. Such growths are usually composed of fibrous tissue; but myxomatous, gliomatous, and sarcomatous tumours have also been described. All neuromata are most common on the nerve-trunks of the extremities, and are generally in great measure separable from the nerve-tubules among which they lie. This is especially the case with the fibrous growths. The so-called *traumatic neuromata* have just been described as 'bulbs' on the proximal end of injured nerves.

Numerous cases of multiple neuromata are on record. In most instances they are confined to one particular set of nerves and their branches. In one case they were confined to the posterior tibial and plantar nerves, and in another to the internal cutaneous and interosseous nerves of the arm. See TUMOURS.

SYMPTOMS AND DIAGNOSIS.—The chief symptom is pain, and this is felt not only at the seat of growth, but also in the parts to which the diseased nerve is distributed. The pain is often of an aching character, but is also at times shooting or neuralgic. Hyperæsthesia or anæsthesia of definite cutaneous areas are less common phenomena, and muscular weakness or paralysis is comparatively seldom complained of. On clinical examination a neuroma will be found as a smooth oval or rounded swelling, varying in size, and situated in the course of a nerve-trunk. The tumour is more movable in the transverse diameter of the limb than in its long axis. Handling and pressure cause pain both locally and in the course of the affected nerve.

TREATMENT.—Neuromata on the continuity of a nerve, if painful or situated so as to be easily accessible, and liable to injury, may be dissected out carefully. Sometimes it will be found that the tumour can be extirpated without taking away the entire thickness and destroying the continuity of the nerve, which, when a large one (as for instance

the great sciatic), it is important to preserve. In case this cannot be done, the whole section of the nerve-trunk may be taken away, and the smoothly cut ends brought together with fine chromicised catgut sutures, the limb being placed in a position to relax the nerve and lessen tension to the utmost. If approximation be impossible, union may be obtained by grafting a portion of nerve, taken from an animal or from a recently amputated limb, between the separated ends.

In cases of neuromata in stumps excision is sometimes available and effective. Opening the cicatrix and dissecting out the tumour or tumours may be all that is required, and this operation should in all cases be combined with thorough stretching of the affected trunks. But in other instances the pain and tenderness are so diffused, and the growths so numerous, that re-amputation a few inches higher up gives more complete and satisfactory results. Special care should be taken that the nerve-ends are cut short, so that they may not be included in or compressed by the scar.

3. Nerves, Surgical Division and Stretching of.

(a) *Nerve-section*.—SYNON. : Neurotomy.—Surgical division of nerves has been employed for the cure of painful affections, such as neuralgia, and for obstinate and sustained spasmodic movements. It has been usually performed subcutaneously, and most frequently in the case of the branches of the trifacial nerve, at their exit from the bony foramina, such as the supra-orbital, the infra-orbital, and the mental branches. Efforts have been directed to prevent the union of the cut nerve, by taking away a considerable portion, so as absolutely to prevent contact of the ends; and the operation then must necessarily lose its subcutaneous character. When the nerve spreads out to its distribution in all directions, it is difficult to secure this absolute removal, and a good deal of the adjacent soft parts must be excised to insure its being done thoroughly. The operation has to a great extent been given up since the introduction of nerve-stretching, and should never be performed until the latter method has been given a thorough trial.

(b) *Nerve-stretching*.—Nerve-stretching is effected by cutting down upon the nerve-trunk, detaching it from its connections for the space of a few inches, laying hold of it with the fingers, or passing an aneurysm-needle beneath it, forcibly stretching the whole nerve from its origin to such an extent as to affect powerfully its functions, and then closing up the wound. In some instances a certain amount of loss of sensation or muscular power in parts to which the nerve is distributed is the immediate result; this, however, passes away after a certain interval, and nerve-function becomes more or less completely restored.

APPLICATIONS.—The most useful application of nerve-stretching is its employment for the relief of neuralgia. In many cases of facial neuralgia temporary benefit at least is secured, while in some a permanent cure results. It is specially indicated in the epileptiform variety of facial neuralgia, and in intractable sciatica. The sciatic nerve can also be efficiently stretched without any incision, by what is known as the 'bloodless method.' For this purpose the patient is placed under an anæsthetic, and, the leg being maintained in a position of extension, the thigh is flexed upon the pelvis, and thus all the structures passing from the pelvis to the

posterior aspect of the thigh are put on the stretch. This condition of tension should be maintained for about ten minutes, and the limb should then be thoroughly massaged, the region of the sciatic nerve being especially kneaded and rubbed.

In cases of old nerve-injury or of implications of nerve-trunks in scar-tissue, the operation of nerve-stretching is most useful, but in all such cases the nerve should be exposed at the seat of injury or of thickening, and should be thoroughly freed with the knife before stretching is commenced.

In cases of motor spasm, nerve-stretching has also been employed, but with less success. Thus, it has been used for the treatment of spasmodic wry-neck, and facial tic or *tic convulsif*. In some cases also of tonic spasm and contracture the operation has appeared to be of benefit. For chronic neuritis, and especially for ascending neuritis, with thickening of the nerve-trunk, nerve-stretching is sometimes of much use, and should always be given a trial.

In tabes dorsalis, nerve-stretching was at one time much employed on the Continent, but has now fallen into disuse. It is, however, probable that some patients derived benefit from its application; and although it is not to be expected that the motor inco-ordination will be cured, yet in cases where the lightning-pains are specially severe the operation is possibly worthy of trial. Nerve-stretching has also been employed with benefit for anæsthetic leprosy, and for reflex epilepsy.

ANTHONY A. BOWLBY.

NERVI, in the Eastern Italian Riviera.—Warm, moist, winter climate. See CLIMATE, Treatment of Disease by.

NERVOUS.—A term used variously in reference to persons, to temperaments, or to morbid conditions. A person is said to be nervous, or of a nervous *temperament*, who seems to present a special susceptibility to pain, or who exhibits an undue mobility, as it is termed, of the nervous system—that is to say, when the person starts or shakes on the occasion of abrupt or intense sensorial impressions, or when he exhibits a proneness to convulsions, or manifests an exalted emotional susceptibility. An organisation of this kind characterises children rather than adults, and, among the latter, females more than males.

In reference to *disease*, the term 'nervous' implies 'relating to the nervous system' or 'affecting' it.

NERVOUS SYSTEM, Physical Examination of.—It is all-important that the physical examination should follow a definite routine, so arranged that the functions of every part of the nervous system may come under investigation. The signs of general diseases of the nervous system (Multiple Sclerosis, Tabes Dorsalis, &c.) may be at first almost entirely local, and some unobtrusive physical sign in a distant part of the nervous system may lead up to the recognition of the nature of the disease. If from an insufficient examination such signs be not discovered, an entirely erroneous diagnosis of local disease may be arrived at. Moreover, in no other system in the body may the presence of a single physical sign so entirely alter the conception of the nature of the disease present.

General Aspect of the Patient.—Careful attention must be paid to the general appearance of the patient at a distance of some yards, as in many

diseases the appearance is striking and may reveal important signs which are not so obvious on closer examination. The facial expression and the attitude of paralysis agitans, the facial expression of tetanus, bulbar paralysis and myasthenia gravis; the 'stiff back' of vertebral disease and the attitude of old-standing hemiplegia are among the very characteristic aspects of nervous disease. Among other signs, which are more obvious at a distance, may be especially mentioned partial bilateral ptosis, partial bilateral facial paralysis, and the position of the head in disease of one lateral lobe of the cerebellum (the head is inclined towards and the face is rotated away from the side of the lesion).

Psychic State.—It must be noticed in conversation whether the patient be a good witness or whether any peculiarity of mental state be present, however slight. Loss of reserve, facility, mental instability, exaltation and placidity, and the occurrence of delusions and hallucinations must be looked for, and any alterations of habit noticed.

Convulsions.—Where these occur it is of great importance that the patient be observed at the moment of commencement of the attack, when the facial aspect and colour should be particularly noticed (*see* EPILEPSY). The commencement of the convulsion should be noticed, whether it is local or general, unilateral or bilateral; its mode of spreading when local, and the extent of the body involved; the nature of the movements, whether tonic or clonic, irregular or purposive; the state of consciousness during and after the attack, whether paralysis succeeds the convulsions, whether there is biting of the tongue or incontinence of the sphincters during the attack. Enquiry should be made into the exact nature of any warning that precedes the attack. It should be remembered that just as recurring convulsions, commencing in one part of the body, may be a sign of a local lesion of the cerebrum (motor centres), so may recurring sudden sensations, both in connection with the special senses and general sensation, be signs of disease in the sensory region of the cerebral hemispheres. *See* CONVULSIONS IN CHILDREN.

Speech and Articulation.—Where disorders of articulation are met with, a careful analysis of the pronunciation of consonants will in slighter cases reveal which part of the articulatory mechanism—tongue, lips or palate—is at fault. The most useful test-sounds for palatal defects are final 'b' and 'g' which are pronounced 'm' and 'ng'; the words 'rub' and 'egg' becoming 'rum' and 'eng'; for lingual defects the explosives 'd' and 't,' which then lose their explosive character, and for labial defects initial 'wh' or 'w' as in 'which went.'

Examination of the more complicated kinds of articulatory defect is rendered easy if it be remembered that they consist always of one or more of the following primary faults: (1) slurring, (2) elision of syllables, (3) stumbling over syllables, (4) reduplication of syllables, (5) undue separation of syllables (scanning).

The repetition of such test phrases as 'Mutual Eligibility,' 'West Register Street,' and 'The Royal Irish Horse Artillery' will reveal the nature of the defect present in any given case.

For the investigation of aphasia and allied speech-defects, the following scheme of procedure is most useful. *See also* APHASIA.

General.—(1) Is the person right or left-handed, and, if the latter, does he write with the right

hand? (2) What is the state of education as regards reading and writing? (3) Does he understand the nature and uses of objects, and can he understand or express his wants by pantomime and gesture?

The activity of the auditory word-centre and the glosso-kinæsthetic centre and their connections.—(4) Is he deaf? If so, to what extent, and on one or both sides? (5) Can he recognise ordinary sounds and noises? (6) Can he comprehend speech? If so, does he at once attempt to answer a question? (7) Is spontaneous speech good? If not, to what extent is it impaired? Does he make use of recurring utterances, wrong words or gibberish? (8) Can he repeat words uttered before him?

The activity of the visual word-centre and the cheiro-kinæsthetic centre and their connections.—(9) Is the sight good or bad? Is there hemianopsia or optic neuritis? (10) Does he recognise printed or written words? If not, does he recognise single letters or numerals? (11) Can he write spontaneously? What mistakes occur in writing? Is there paraphasia? Can he read his own writing some time after it is written? (12) Can he copy written words, or from print into writing? Can he write numerals or perform simple mathematical calculations?

The associated activity of the speech-centres.—(13) Can he read aloud? (14) Can he name at sight words, letters, numerals, and common objects? (15) Can he write from dictation?

Special Senses.—1. *Smell.*—Only those substances which are readily oxidisable, such as the volatile oils, affect the terminations of the olfactory nerve. These are perceived as *odours* if they reach the terminations of the olfactory nerve through the anterior nares; as *flavours* if their path is by the posterior nares. Pungent substances, such as ammonia and acetic acid, stimulate the fibres of the fifth nerve, which supply the nasal chambers with common sensation, and such substances may be perceived when smell is entirely lost. For the testing of the sense of smell, such substances as peppermint, asafetida, clove, and camphor are most convenient. Each nostril must be tested separately while the other nostril is closed with the finger, as anosmia is frequently unilateral. *See* OLFACTORY SENSE; and NOSE, Diseases of.

2. *Vision.*—Each eye must be tested separately as regards perception of form, perception of colour, and visual field. The refracting media and fundus must be examined (*see* OPHTHALMOSCOPE; OPHTHALMOSCOPE IN MEDICINE; and EYE, Diseases of). Where vision is greatly reduced perception of light alone can be tested. For perception of form Snellen's test-types should be used, or where only a little vision remains it should be ascertained at what distance the patient can count fingers held up against a strong light. McHardy's self-registering perimeter is most convenient for determining the visual fields. It must be used accurately and a reading taken at every five degrees around the visual field. Reliable information, however, can be obtained without the use of instruments in the following manner. One eye of the patient is closed, either with his hand or with a bandage, and he is directed to look intently at the observer's nose from a distance of two feet. A piece of white paper, half an inch square, held upon a long penholder by being thrust into the slit of the nib, is brought into the patient's field of vision from the periphery in each part of the field. Coloured papers are then

used in place of the white paper, and the fields for the various colours determined.

Loss of perception of colour, hemianopia, quadrantic hemianopia, hemi-achromatopsia, general contraction of the visual fields, crossed amblyopia, helicoid (spiral) fields and central defects (*scotomata*) are to be looked for and may be readily demonstrated by this rough method. The presence of hemianopia may also be detected by means of the pressure-phosphene. If the point of a pencil be pressed firmly against the eyeball, close to the orbital margin, a ring of light is perceived in the opposite part of the visual field; consequently when part of the visual field is lost the phenomenon is absent from the corresponding part of the eyeball. Where detailed examination is impracticable, hemianopia may be detected by standing in front of the patient, who is directed to look straight forwards. The observer then holds up both hands, one on either side and slightly in front of the patient's head, and directs him to touch his hand. The hemianopic patient at once touches the hand he sees. If there be no hemianopia the patient

bringing a watch from a distance towards the ear, the other ear being closed with the finger. Perosseal conduction is investigated by applying a tuning-fork with a disc-shaped foot to the zygoma or mastoid process, the external auditory meatus of the same side being closed with the finger.

Where aerial conduction is much impaired or lost while perosseal conduction remains good, the fault lies in the external auditory meatus (cerumen) or the tympanic ossicles and membranes, and not with the nervous apparatus. Where both aerial and perosseal conductions are impaired or lost (nerve-deafness) there may be primary disease of the nerve, or it may be damaged from disease in its immediate neighbourhood (tumour, meningitis, &c.), in which case the contiguous facial and fifth nerves may be affected. Relative deficiency in the appreciation of tone must be tested with Galton's graduated whistle.

4. *Taste*.—This sense should be tested by means of sugar, common salt, tartaric acid, and quinine applied in the form of powder by means of a moistened camel's-hair brush to the back and front

FIG. 1.—Position of images in the binocular field in cases of paralysis of the left third nerve (III), and left sixth nerve (VI) respectively. The thin arrow denotes the false image.

inquires which hand he is required to touch. In a semi-conscious patient the presence of hemianopia may be considered probable if, when a feint is made from the side at either eye (the patient's eyes being open), he constantly winces when the attempt is made from the right and never when it is made from the left, or conversely. Care must be taken, however, in this procedure that the movement of the hand in making the feint causes no draught of air to strike the conjunctiva. When hemianopia is present it must be determined whether this is due to disease of the optic tract or of the occipital lobe by means of Wernicke's reaction. A strong ray of light is thrown on to the blind side of the retina; if the pupil reacts, the reflex fibres of the pupil which separate from the optic fibres at the posterior end of the tract are uninjured, and the disease is presumably not situated in the optic tract but in the occipital lobe. On the other hand, if the pupil does not react it is probable that the situation of the lesion is in the region of the optic tract.

3. *Hearing*.—Perception of sound through the air (aerial conduction) should be tested by gradually

of each half of the tongue, while that organ is at rest in the mouth. Some normal people are entirely unable to taste on the protruded tongue. The sentient areas on the anterior part of the tongue are a small patch on the lateral margin of the tongue on either side near the tip, while the posterior sentient area is far back in the region of the circumvallate papillae, the rest of the tongue being more or less insentient for taste. The velum palati and the glosso-epiglottic folds also contain taste-organs. The nerves for taste leave the brain in the fifth nerve, those for the anterior two-thirds of the tongue, leaving the pons by the second division of the fifth nerve, pass in order by the vidian, great superficial petrosal, facial, chorda tympani and lingual nerves to their distribution, while those for the posterior two-thirds of the tongue and for the palate pass from the fifth into the glosso-pharyngeal trunk; their course has not been demonstrated with certainty.

Other Cranial Nerves.—*Oculo-motor nerves*. The condition of the pupils should be examined as to size and shape, and as to the presence of signs of iritic adhesions which may interfere with the

mobility of the pupil. Both the direct and the consensual light-reflex (the contraction of the pupil of the opposite eye when one eye alone is exposed to light) should be tested, and the light employed should be bright and at some distance from the patient in order to avoid the contraction of the pupil associated with convergence. It should also be noticed whether the pupils dilate when shaded, to an equal extent in both eyes. The contraction of the pupil which occurs when a near object is fixed is associated with the act of convergence and not with the act of accommodation, for when the act of accommodation occurs without convergence there is no associated contraction of the pupil. The condition of the ocular movements should be tested in the following way: the patient is directed to look at an object on a level with his eyes and about a yard in front of his face, and it is noticed whether there is a strabismus present. If so, first one eye alone, and then the other alone, is covered, yet so that the eye can be observed, and it is found that when the normal eye is covered, the erring eye moves in the direction of the weak ocular movement to fix the object. The object is then moved upwards, downwards, and in either lateral direction, until the extremes of possible deviation of the eyes are produced, when weakness of any particular movement will become apparent. Any defective movement involving the corresponding movements of both eyes (as for instance lateral deviation to one side) must be specially noticed; the cause of such defect is always nuclear in situation. Where diplopia is present and the strabismus not very obvious, it is useful to take a chart of the position of the true and false images of an object, such as an arrow drawn on white paper in the binocular field (see fig. 1). By this means the nature of a diplopia becomes at once clear. It is convenient to remember that when from a strabismus the prolongations forward of the optic axes cross (convergent strabismus), the resulting diplopia is homonymous (false image on the same side as erring eye); when the axes diverge, the resulting diplopia is crossed (false image on the same side as sound eye).

Rotatory movements of the eyeball, occurring with certain movements of the eyes, must be looked for where paralysis of either the superior or inferior oblique muscles is suspected. In some ocular palsies characteristic attitudes of the head are assumed in order to avoid diplopia; for instance, in palsy of the inferior oblique the head is often thrown back. The presence of ptosis or of von Graefe's sign must be looked for, and the width of the palpebral aperture examined. The effect of local instillation of cocaine upon the pupil, and width of the palpebral aperture, are important in investigating paralysis of the cervical sympathetic trunk (*vide infra*).

Nystagmus.—It should be noticed whether this sign is present when the eyes are at rest (spontaneous nystagmus) or only on movement of the eyes. The range and nature of the nystagmus should be examined. See NYSTAGMUS.

The Fifth Nerves are to be examined by testing the condition of sensibility of the face and mucous membranes of the mouth and nose (*vide infra*) and by testing the power of the masticatory muscles supplied by that nerve. The observer's fingers are pressed firmly against the temporal muscles or the masseters on both sides, and the patient is directed

to bite 'as if he were cracking a nut.' From the amount of bulging of these muscles during the contraction, deficiency on one or both sides may be proved. Weakness of the mylo-hyoid and anterior belly of the digastric is detected by pressing upwards on to the floor of the mouth with both thumbs, while the patient opens his mouth forcibly; the floor of the mouth hardens only on one side in unilateral paralysis of the fifth nerve. From the unopposed action of the external pterygoid muscle of the sound side, the jaw, when the mouth is open, deviates strongly to the paralysed side when there is unilateral paralysis of the fifth nerve. Hollowing of the temple and flattening of the cheek, from wasting of the muscles of mastication, are readily detected. The affection of taste has been mentioned above. Smell may be ultimately lost on the side of the injured nerve from slow trophic changes occurring in the olfactory mucous membrane. Facial anaesthesia should be looked for where there is corneal ulceration.

Seventh Nerve.—The various regions of the face must be investigated as regards (1) volitional movements, such as closing the eyes against the resistance of a finger placed upon the lid, or showing the teeth; (2) emotional movements, such as those produced by the request for 'a pretty smile'; and (3) associated movements, such as are observed in the lower face when the eyes are forcibly closed. See FACIAL PARALYSIS.

Ninth, tenth and eleventh Nerves.—These may be considered together, as they constitute a physiological group, and are frequently involved together by a lesion situated at the side of the medulla. They are the sensory and motor nerves of the palate, pharynx, oesophagus and larynx. The eleventh nerve also supplies the sterno-mastoid and trapezius in part. The palatal and pharyngeal reflexes depend upon the integrity of these nerves. Sensibility and motion are to be examined in the usual way. See LARYNX, Examination of.

Twelfth Nerve.—The power of the tongue is best tested by the ability to protrude it and to put it into either cheek. Fibrillation and wasting are to be looked for, and when the latter is present the muscles should be examined with electricity, very weak currents being used. In unilateral palsy of the tongue the tip always deviates towards the paralysed side.

Cervical Sympathetic Nerve.—Pathological conditions of this nerve are frequently overlooked, and signs of these should always be sought for (1) in cases of ocular paralysis, (2) where disease of the cervical cord is suspected, and (3) in syringomyelia. A small pupil which does not dilate to cocaine, narrowing of the palpebral aperture, and unilateral flushing and sweating of the face are signs of paralysis of the sympathetic.

Von Graefe's symptom, retraction of the upper eyelid, a large pupil and tachycardia indicate an irritative lesion. Not uncommonly symptoms of paralysis and irritation are alternately present.

Sensation.—The occurrence, nature and exact distribution of subjective sensations, pain, numbness, tingling, &c., and any circumstances causing their exacerbation, must be considered. Such sensations occurring in areas corresponding with the distribution of special nerve-roots or nerve-trunks are of great value as spinal localising symptoms. The girdle-sensation of common occurrence in local disease of the spinal cord, the sense of weight in

the perinæum in tabes, and the 'hide-bound' feeling in the limbs, are examples of subjective sensations of segmental distribution; while the distribution of the pain in trigeminal neuralgia and in sciatica are examples of nerve-trunk sensations.

The accurate objective investigation of sensory disturbances is by far the most laborious and difficult part of the physical examination of the nervous system, for the observer is entirely dependent for his information upon the statements of the patient, and for this reason dulness of attention and the fatigue of a long examination are apt to introduce fallacies. The patient's eyes should be screened from the action of the investigator.

Sensibility to Touch is tested by degrees of pressure with the finger. A more delicate test for examining the slightest changes is to brush the skin gently with a small skein of silk, wool and linen successively. A normal person perceives the difference in the contact of these materials at once. *Sensibility to Pain* is tested with a pin, which should be presented to the skin together with a comparatively large touching surface—for instance, the top of the investigator's finger—lest from the small area of contact the pin is recognised as such where sensation to pain is absent. *Sensibility to Temperature* may be tested by the application of test-tubes containing hot water and iced water respectively. It must be borne in mind that an anæsthetic skin will blister readily on the application of heat. *Sensibility to the Faradic current* is best examined by applying to the skin a pair of wire electrodes such as are in common use in physiological laboratories.

The following course of procedure is absolutely essential if reliable information is to be obtained. The investigation is commenced upon an area where sensibility is normal, and is carried out first in straight lines running in the direction of the length of the body, and secondly, in lines at right angles to these until the whole surface of the body has been tested. Working thus from æsthesia to anæsthesia the points at which the least change is noticed are to be taken as the limit of sensory impairment; and should be marked upon the body with a dermatographic pencil and subsequently filled in upon a chart. The results obtained should be carefully compared with the diagram of segmental areas (see PAIN IN VISCERAL DISEASE). When anæsthesia is partial the power of localising sensory stimuli must be tested. Hyperæsthesia, delayed sensation and allocheiria (p. 48) must be looked for.

Muscular Sense.—Abnormal conditions of this sense may be detected by the examination of (1) the sense of passive position, (2) the sense of active muscular contraction, and (3) the power of maintenance of position.

To test the sense of *passive position*, the patient is blindfolded and the limb is placed by the observer in various positions, which are then indicated by the patient, and in order to avoid inferences that the subject may gain from cutaneous sensation during this process, the limb (a finger, for instance) should be held laterally between the thumb and index-finger of the observer. The sense of active *muscular contraction* is best measured by appreciation of weight. A series of leather-covered balls of equal size and different weights are made for the purpose. Where the muscular sense is impaired

appreciation of differences in weight becomes extremely defective (for other tests see ATAXY, p. 1068). The power of *maintenance of position* is tested in the following manner. The patient is directed to hold his arms straight in front of him, with the fingers spread out. He is then directed to close his eyes, when, if the muscular sense be much impaired, wandering movements of the limbs soon commence, of which the patient is entirely unaware.

The Motor System.—The performance of the complicated voluntary movements to which the various parts of the body are accustomed are first to be observed, for while there may be no discernible paralysis of any muscle in detail, there may be striking paralysis in effect when an attempt is made to perform any complicated act. A patient who, when lying in bed, can make all the movements of the lower extremity powerfully, may show great motor defect in that same limb when attempting to walk, and similarly in writer's cramp the hand may be almost completely paralysed for one kind of action only. In investigating such actions, as, for instance, the patient's gait, scrutiny should be used lest a defect appeal to the observer as a generic idea. As an instance, a patient may be said to stagger when walking; such a description conveys little information, since it may be caused by general asthenia, cerebellar disease, labyrinthine disease, spasticity of muscles or loss of muscular sense; careful analysis, however, will reveal the nature of the defect. The power of each group of muscles should be tested in terms of the performance of some movement against resistance or gravity—a certain movement is possible or not against a certain resistance. The dynamometer should be used, where possible, for by its means the progress or decrease of muscular weakness can be accurately gauged. Localised and general wasting or hypertrophy of muscles should be noticed. Measurements are most correct if the maximum and minimum circumference of a limb be recorded.

The presence of *deformities* due to muscular spasm, paralysis or contracture, the occurrence of *tremor*, *fibrillary twitching*, *rigidities*, *hypotonus*, *muscular tenderness*, and the *excitability* of the muscles to mechanical stimuli (i.e. direct percussion) must be investigated.

Hypotonus.—The signs of this important condition, to which great attention has of late been drawn, are worthy of special notice here. The condition is the opposite of rigidity, it is more than mere flaccidity. The muscles hang loosely from the bones, the joints rattle when shaken, and can be moved 'like loosely sewn-on buttons.' Attitudes like those of an acrobat, which are impossible in normal persons, can be assumed without discomfort: for instance, the thigh can be flexed until the tibia touches the clavicle; the thighs can be spread until they form a straight line with one another at right angles to the trunk; the patient sitting upon the floor can bend forward and touch the ground in front of him with his head when this condition is present in severe degree.

Hypotonus is dependent upon a condition of relaxation of both muscles and ligaments. Its presence implies neither wasting nor paralysis, and sometimes even there may be increase of the deep reflexes. It is always present in some degree in cases of tabes dorsalis. The presence of this sign usually signifies disease of the posterior columns of the cord.

Electrical Reactions.—It is, as a rule, only necessary to examine the electrical excitability of the muscles where wasting or muscular tenderness is present. The all-important point is whether faradic excitability is present, reduced or absent. This is best tested by means of single induction-shocks. Two small electrodes should be applied, without regard to motor points, directly to the surface of the muscle. Single induction-shocks are infinitely less painful than is the interrupted current. For the examination of electrical reactions in children an anæsthetic should always be employed. *See* ELECTRICITY IN MEDICINE.

Individual Muscles.—Space does not permit of the enumeration of the tests of the power of individual muscles, but on account of the importance of weakness of the trunk-muscles, as localising signs of spinal-cord lesions, the methods of their examination are here mentioned.

Erector Spinae.—The patient is seated upon a stool and the head and trunk being flexed to the full, he is directed to raise his head and trunk to the vertical position against the resistance applied with the hand to the back of his head. During this action the observer feels with his hands the hardening and bellying of the erector spinae in its various parts. If the examination is to be carried out upon a patient who must remain in bed, he is placed in the prone position, the pillows being removed, and he is directed to raise his head backwards off the bed without using the upper extremities.

Respiratory Muscles.—Paralysis of the intercostal muscles is recognised by the loss of the expansive movement of the upper eight ribs during inspiration. The movement of elevation is carried out chiefly by the scalene muscles, and in intercostal palsy there is frequently visible action in the auxiliary muscles elevating the chest (sterno-mastoids, infrahyoid muscles, &c.). The eversion of the lower four ribs during inspiration is carried out by the diaphragm, and is frequently present where the intercostal muscles are completely paralysed, and must not be mistaken for intercostal action. Paralysis of the diaphragm is shown by the loss of the inspiratory expansive movement of the abdomen and by the eversion of the lower ribs. The abdomen is sucked in during inspiration, and the normally synchronous expansive movements of the chest and abdomen then alternate.

Abdominal Muscles.—The patient is directed to raise himself in bed from the supine position without using his hands, and the surface of the abdomen is noticed. This act is impossible when any severe degree of weakness of the abdominal muscles is present. When a local lesion of the spinal cord in the region of the supply of the abdominal muscles is present, the appearance of the abdomen during the attempt is characteristic. If there be weakness in the lower parts of the abdominal wall the umbilicus shifts upwards; and if weakness be confined to the upper abdominal wall the umbilicus shifts downwards, and the exact limit of the paralysed muscle may often be determined by the formation of marked retraction-line. (The abdominal musculature is supplied by the lower six dorsal and first lumbar nerve-roots. The umbilical region is supplied by the ninth dorsal root.) Local paralysis of the rectus abdominis and of the oblique muscles is evidenced by vertical and lateral bulging of the abdominal wall respectively during the attempt to sit up.

Ataxy.—Tests further than those given under the heading 'Muscular Sense' are for the upper extremity: (1) the handwriting; (2) picking up a small object, such as a pin, from a flat surface; (3) touching the nose with the index finger of either hand, with the eyes first open and then shut. For the lower extremities, the following tests are convenient: (1) touching the observer's finger, held within easy reach, with the great toe, the eyes being open; (2) placing the heel of one foot upon the knee of the opposite side, the eyes being closed. (These tests, 1 and 2, are of service when the patient is unable to stand.) (3) Standing upright with the feet together, with the eyes open; and (4) with the eyes closed (Romberg's sign); (5) standing upon one foot; (6) walking along a straight line; (7) and, as the most delicate test of all, 'toeing and heeling' a line.

Trophic Disturbances.—Attention must be paid to the occurrence of brittle and 'reeded' nails, thin and glossy skin, induration and desquamation of the skin, localised or general atrophy of the skin, leucoderma, bedsores, perforating ulcer, herpes and local cutaneous hæmorrhages, thickening of bones, arthritic changes (adhesions, grating, Charcot's joints, &c.).

Vaso-motor Disturbances.—The following points should be noticed: the occurrence of local flushing, erythromelalgia (p. 491) or cyanosis, local elevation or depression of surface-temperature, clubbing of the fingers and toes and localised sweating.

Pelvic Reflexes.—Trouble in the performance of the acts of micturition and defæcation should be most carefully inquired into. Slight troubles of this nature are often concealed by patients, especially by women. The exact nature of such defect, whether hesitation, precipitancy, retention, or reflex or paralytic incontinence must be ascertained. The bladder should be examined by palpation and percussion after a natural evacuation in every case where there is dysuria, to ascertain whether there be residual urine—an important predisposing cause for cystitis. The use of the catheter for this purpose, even though the greatest care be used, is apt to set up cystitis.

Where incontinence is complete, the sphincter ani should be examined digitally, to ascertain if there be reflex contraction or not. Reflex contraction of the bulbo-cavernosus muscle may be tested by pinching the skin of the perineum while the finger rests upon the bulb of the urethra.

Defects of sexual power are important: they are said to be constantly associated with defective sensibility of the glans penis.

Reflex Action.—The following superficial reflexes should be examined. The *corneal reflex* is best tested by suddenly blowing upon the patient's face. To obtain the *pharyngeal reflex*, the tongue is depressed and the posterior wall of the pharynx and lower edge of the soft palate are stroked with a pen-holder, and the contraction of the palate and pharynx observed. The *abdominal* and the *cremasteric* and *dartos reflexes* are obtained by stroking the skin lightly over the lower ribs and groin respectively. The *plantar reflex* should be investigated, if possible, when the foot is neither damp nor cold, the knee should be flexed and rolled out, and a light scratching stimulus should be applied from heel to toes, across the sole, and the movement of the toes, whether flexor (normal) or extensor (abnormal, and indicating a lesion of the pyramidal

tract) should be observed, and also whether the tensor fasciæ femoris is the first muscle to contract in the reflex (normal). See BABINSKI'S SIGN.

Tendon-Phenomena.—These phenomena are obtainable in those muscles of the body which are suitably placed for examination. The following should be examined in every case. A heavy wooden stethoscope, with a soft indiarubber-ring fitted round the ear-piece, is the most convenient instrument to use.

1. The *jaw-jerk* is best obtained by allowing the jaw to hang loosely. Percussion is then made downwards, either upon a rigid article, such as a paper-knife, placed upon the lower teeth or upon the observer's finger, which rests upon the chin. Jaw-clonus is produced in the same way, and is evidence of increase of the myotatic irritability of the muscles of mastication.

2. The *forearm-jerk* is produced when the radial border of the forearm is struck with a hammer, the elbow being flexed at a right angle, and the hand supported by the observer so as to ensure complete muscular relaxation.

3. The *triceps-jerk*.—The arm is abducted at the shoulder to the horizontal, and held by the observer immediately above the elbow, the forearm is allowed to hang vertically downwards, the tendon of the triceps is then struck immediately above the olecranon. Care must here be taken lest the muscle of the triceps be struck, and direct muscular contraction (which is an entirely distinct phenomenon) be mistaken for the tendon-jerk.

4. The *adductor-jerk* is obtained when the internal condyle of the femur is struck heavily in an outward direction, the hip and knee being slightly flexed and rolled out. Sometimes a response in the adductor muscles of the opposite thigh is obtained (crossed adductor-jerk).

5. The *knee-jerk*.—The knee should be bared and resting, without muscular exertion, in a position of flexion, the tendon should be struck exactly in the interval between the lower border of the patella and the tuberosity of the tibia. In rare cases of isolated atrophic palsy of the quadriceps, the knee-jerk being absent, percussion of the patellar tendon causes contraction in the ham-strings (flexor knee-jerk).

6. The *depressed patella-jerk* is obtained with the leg extended and the quadriceps flaccid, the upper border of the patella is pressed down forcibly with the index-finger hooked round it, and the finger is then struck in a downward direction with a hammer.

7. The *Achilles-jerk*.—The observer seizes the fore part of the foot with the left hand and raises the whole limb, pressing the foot back so as to make the tendo Achillis taut; the tendon is then smartly and lightly struck with the hammer.

Methods of Reinforcement.—In order to ensure muscular relaxation, to remove the element of expectant attention, and actually to increase the activity of the tendon-phenomena, certain proceedings should always be adopted: (1) In general reinforcement the patient is directed to look away from the observer; he is engaged in conversation; he is directed to squeeze his hands together with all the effort he can muster, or to perform some other act requiring effort, with any one of the limbs that is not being investigated, while the tendon-phenomena are being tested. Where the tendon-phenomena are much diminished, sensory stimulation, such as friction to the skin, the application of faradism and especially a cold shower-bath, tends to

increase the tendon-phenomena, and the effect is most marked about five minutes after such stimulation. (2) Local reinforcement is used for the investigation of the knee-jerk only. The foot is passively pressed back, and the patient is directed to press gently against the resistance with his toes. Severe muscular rigidity and arthritic changes may make the tendon-phenomena impossible to obtain.

Clonus.—Where the tendon-phenomena are exaggerated clonus may be obtained in almost any muscle by suddenly stretching it. Foot-clonus, rectus-clonus, and hand-clonus are most commonly investigated. The least movement of a limb may set up a general clonus (spontaneous clonus, epileptoid spasm).

Spurious Clonus.—Foot-clonus not infrequently occurs in cases of functional disease. Attempts have been made to separate this form of foot-clonus from that occurring in organic diseases under the above term. While this is certainly impossible, yet in some functional patients a form of foot-clonus *sui generis* is met with, and has the following distinctive features: (1) It is often irregular in rhythm; (2) the position of the foot during the occurrence is one of moderate plantar extension (in organic clonus the position is one of dorsiflexion); (3) the clonus is started by a voluntary movement of plantar extension on the part of the patient, and not by sudden passive stretching of the muscle. This useful sign was described by Beevor. In many normal persons clonus of this nature may occur when sitting in certain positions.

The examination of the skull, vertebral column, heart, pulse, temperature, respiration and other parts and phenomena is of great importance in cases of nervous disease. See PHYSICAL EXAMINATION. JAMES COLLIER.

NERVOUS TEMPERAMENT.—See NERVOUS; and TEMPERAMENT.

NETTLE-RASH.—A popular synonym for urticaria. See URTICARIA.

NEUENAUHR, in Germany.—Thermal alkaline waters. See MINERAL WATERS.

NEURALGIA (νεῦρον, nerve; and ἀλγία, I suffer pain).—**SYNON.**: Fr. *Néuralgie*; Ger. *Neuralgie*.—This is a term applied to a disease of the nervous sensory apparatus, marked by paroxysmal pain, which is for the most part unilateral, and in the course of a nerve or its branches. In many cases no evidence of change in the periphery of the nerve is discoverable, and to these the term *neuralgie* is perhaps most properly applied; in others, however, there is reason to think that inflammation of the nerve is at least the starting point of the disorder. The diagnostic points are as yet not sufficiently certain for these cases of neuritis to be absolutely separated from those of simple neuralgia, and they may so far be considered together. Relative constancy in the pain, with paresis and atrophy of muscles supplied by the affected nerve, cutaneous anesthesia, and swelling of the nerve-trunk, point to neuritis. See NEURITIS.

ÆTIOLOGY.—Neuralgia is prone to occur in families marked by neurotic tendencies, not necessarily of neuralgic character, but which display themselves in various phases of psychical disturbance, as insanity, hysteria, hypochondriasis, or in the shape of epilepsy, neurasthenia, and chorea.

Rare in childhood, puberty has a strong predisposing influence. In the middle period of life, though first attacks are not very common, revivals of neuralgia are apt to occur, as a result apparently of the depression occasioned by the wear and tear of life. Premature senility (marked by atheromatous changes in the vessels, arcus senilis, permanent greyness of hair, bagging of the cheeks, pulmonary emphysema) conduces to severe and intractable neuralgias. Malaria is a potent cause. The presence of sewer-gas in a house may occasion persistent neuralgia. Anæmia and malnutrition generally, however brought about, play an important part. So also do sexual excesses, and perhaps likewise a state of celibacy. Pregnancy, over-lactation, and menorrhagia are each predisposing causes. The most frequent exciting causes are cold, especially damp cold; injury to the nerve by violence, or by the encroachment of morbid growths; syphilis; gout; and the presence of lead or mercury in the system. Over-strain of mind or body conduces to attacks. Irritation of peripheric organs may excite neuralgia in nerves nearly or remotely associated. So dental caries may induce supra-orbital neuralgia; indigestion may excite anginal symptoms; uterine disease may excite neuralgia of distant nerve-trunks—as, for example, the occipital; and the presence of intestinal worms may explain the occurrence of neuralgia in parts quite unconnected with the bowels. Neuralgia is a common sequel of enteric fever, relapsing fever, and influenza. Neuralgic pains are prone to occur in the course of diabetes mellitus. They are symmetrical, and are very likely due to multiple neuritis.

ANATOMICAL CHARACTERS.—In simple neuralgia no definite lesions are discoverable—at least, none that are constant enough to deserve the place of necessary accompaniments or factors of the disease. As a result of neuritis or perineuritis the nerve-trunk is sometimes found swollen and hyperæmic; or, in a later stage, it may be atrophied and its fibres degenerated.

SYMPTOMS.—After some little preceding numbness, cutaneous anæsthesia, or other abnormality of sensation, the import of which gets to be well understood by persons liable to neuralgia, the patient is seized with pain, which at first is not severe, and ceases quickly, but returns in a few seconds or minutes, lasting for a short time and then remitting. These darts revive with shorter and shorter intervals, so that in a little time the pain appears to be almost continuous, or interrupted only by waves of increased intensity, and it will last for some seconds or more than a minute together. Then comes a respite, to be followed by recurrence, and these alternations may continue for a few minutes or as many hours. In attacks of long duration, where no treatment is applied, the pain gradually gets less acute, the intermissions longer, and the outbreak passes into a confused feeling of discomfort and bruising about the seat of pain, coupled with a sense of exhaustion and desire for sleep. The character of the pain varies; it is described as darting like a knife or like lightning, crushing, hammering, boring, and sometimes burning. In neuralgia about the head the patient will often be seen to cringe and recede before the plunges of pain, as though he were receiving blows. When the pain is at its worst there is often a radiation of it to other nerves, and especially to those placed symmetrically with the one affected;

but this secondary pain never attains anything like the severity of the original. Not always, but perhaps commonly, certain definite points where pressure is exceedingly painful may be found by palpation. These, the *points douloureux* of Valleix, have a certain amount of diagnostic importance. Rare in first attacks, they are more common in patients who have been subject to recurrences during many years. There is always a nerve-branch under the skin at these points; and more often than not they correspond with the point of emergence of a nerve from a bony groove or opening, or its passage through a muscular aponeurosis. Pallor of the skin followed by intense redness, horripilation, and other evidences of vaso-motor disturbance, are common. In the case of nerves being attacked which preside over glands there is often increased secretion. The tactile sensibility of the skin is almost always diminished after a time in the neighbourhood of the affected nerve, though at first there is some hyperæsthesia. In neuralgia of the fifth nerve spasmodic contraction of facial muscles, of reflex origin, is apt to occur.

LOCAL VARIETIES.—The varieties of neuralgia are divided into two primary groups, namely: I. Superficial; and II. Visceral.

I. Superficial.—These include the following:

(a) *Trigeminal neuralgia.*—See TIC DOULOUREUX.

(b) *Cervico-occipital neuralgia.*—The posterior branches of the first four pairs of spinal nerves may be affected, but it is that of the second, the great occipital, which is most important, from its size, and the frequency with which it is attacked. Shooting pains start from just below the occiput, and run over the back and top of the head, sometimes into the external auditory meatus, and often to the front of the head and face. A point of great tenderness is to be found over the exit of the great occipital nerve. Giddiness, noise in the ears, and some confusion of ideas are often associated, and frequently cause cervico-occipital neuralgia to be mistaken for commencing organic disease of the brain. It may begin by such acute tenderness of the scalp as makes it an agony to brush the hair.

(c) *Cervico-brachial neuralgia.*—The nerves of the brachial plexus and the posterior branches of the four lower cervical nerves are here concerned. The pains affect the neck and shoulders, or shoot down the arm to the hand, in the course of one or more of the nerve-trunks. Painful points may be found in the axilla, over the upper part of the deltoid, at the bend of the elbow, three inches above it externally, in the groove between the inner condyle of the humerus and the olecranon, at the ulnar side of the annular ligament, and where the radial nerve becomes superficial. The ulnar nerve is that most often affected, but the neuralgia usually spreads to other trunks. See p. 170.

(d) *Dorso-intercostal neuralgia.*—See INTERCOSTAL NEURALGIA.

(e) *Lumbo-abdominal neuralgia.*—Here the superficial branches of the lumbar plexus distributed to the abdominal walls are affected. It is less common than intercostal neuralgia, but resembles it generally. The female sex is apt to be most affected. Tender points may be found close to the spine, at the middle of the crest of the ilium, in the hypogastric region, in the groin, and on the scrotum.

(f) *Crural neuralgia.*—This variety is almost always met with as a complication of sciatica, being

rare by itself. Pain occurs in the front of the thigh and knee, and inner surface of the leg and foot. The long saphenous branch of the anterior crural nerve is most commonly affected. This form of neuralgia is not infrequent in hip-joint disease, where it is secondary to irritation of the branches of the obturator nerve supplying the joint.

(g) *Obturator neuralgia* affects the inner side of the thigh.

(h) *Femoro-popliteal neuralgia*.—See SCIATICA.

(i) *Coccygodynia*.—Pain in the neighbourhood of the coccyx, especially apt. to occur in women, is sometimes, but by no means always, due to neuralgia of the coccygeal plexus. See COCCYGODYNIA.

II. **Visceral**.—(a) *Cardiac*.—A certain proportion of the class of cases called angina pectoris depends upon cardiac neuralgia (see ANGINA PECTORIS). There is sudden severe pain at the lower end of the sternum, darting to the back and down the left arm, or it may be diffused over the chest and affect both arms. The heart feels as though it were grasped, the face loses colour, the pulse becomes altered in character, there is cold sweating, and generally the aspect and feeling of approaching death. Such attacks may be confined to two or three repetitions, or there may be a constant tendency to their recurrence under circumstances of fatigue or strong emotion. See PAIN IN VISCERAL DISEASE.

(b) *Uterine and ovarian neuralgia*.—Pain attendant upon menstruation, independent of any mechanical difficulty, is thus named. It may be excited by such sources of peripheral irritation as ascariides, leucorrhœa, renal calculus, prolapsus uteri, tumours, ulceration of the cervix, or impaction of fæces; or the sources may be in some distant part of the body. Ovarian neuralgia may be accompanied by congestion of the ovary.

(c) *The urethra, bladder, rectum, kidney*, and *testis* may each be affected by neuralgia. The last-named may result from self-abuse, or be consequent upon renal concretion. See NEPHRALGIA.

(d) *Gastralgia*.—Abdominal neuralgia is characterised by intensity of colicky pain, occurring in paroxysms, in circumstances differing from those which induce ordinary dyspepsia. There is nearly always a history of neuralgia in some other part of the body. Vomiting sometimes, and constipation invariably, accompanies the attacks. See STOMACH, Neuroses of.

COMPLICATIONS AND SEQUELÆ.—Neuralgia when it attacks mixed nerves may produce muscular powerlessness, which is not merely due to a shrinking from making muscular effort because of the pain attending it, but a temporary paralysis consequent on suspension of motor impulses. Or there may be spasm of muscles. Long-continued neuralgia is attended by more or less atrophy of the muscles supplied by the affected nerves, which may be temporary, or, in cases where frequent recurrences of the attack take place, may be permanent. Certain forms of neuralgia, especially that of the first division of the fifth, intercostal, and sciatic nerves, are liable to be accompanied by a herpetic eruption (see p. 685). Anæsthesia of a portion of the skin will often persist, though the pain itself may be absent. Neuralgia tends to become a chronic disorder, with frequent intervals of more or less long-lasting exemption. It does not often appear as an acute attack of suffering, lasting for weeks or months and never returning. Such a history points

rather to neuritis. Long continuance of severe neuralgia may lead to melancholia, which is sometimes of suicidal character.

DIAGNOSIS.—It is of extreme importance that pain should not be attributed to neuralgia until the existence of an organic lesion capable of causing the sensory disturbance has been excluded by the most careful examination. It may be said perhaps that for pain to be strictly accounted *neuralgic* there should be no obvious cause for it, such as fever, local inflammation, tumour, or injury; it should be intermittent, or at least liable to great exacerbations, and independent of movement or any external agency; it should take the course of one or more nerves; and there should be spots painful to pressure in some of the localities already indicated. Neuralgia is distinguished from myalgia by the latter involving the attachments of a muscle, not occurring in paroxysms, but dependent upon movement; from aneurysm by careful physical examination, which is especially necessary when the pain is about the chest and loins. In chronic rheumatism the pain is diffused, and influenced by movement; and it does not affect the district of a particular nerve. Acute rheumatism is accompanied by elevation of temperature, sweating, and swelling of joints. The thermometer, and the known symptoms and signs of the several diseases, will usually at once exclude pleurisy, pneumonia, and peritonitis. Attacks of neuralgia, especially of the supra-orbital nerve, may be characterised by a remarkable periodicity, recurring daily at the same hour, and lasting about the same time, quite independent of any malarial basis. Syphilitic periostitis is evidenced by the sight and touch, as well as (if it occur early in the disease) by the presence of febrile symptoms. Where pain in the back is supposed to be of neuralgic origin it is important to exclude the presence of hernia. Examination should be made *per vaginam* to exclude flexions or tumours of the uterus, and *per anum* for the presence of abscess about the rectum or of malignant disease. Organic disease of the brain must be excluded by the absence of local palsy, vomiting, intellectual disturbance, and optic neuritis. The pains of Bright's disease must be carefully excluded by search for albumen, signs of arterial thickening, and cardiac hypertrophy. So-called spinal irritation is accompanied by pains, which, however, fail to mark the district of particular nerves, and are vague and shifting. There is hyperæsthesia of the skin over some of the vertebral spines. Locomotor ataxy is characterised by pains of lightning-like rapidity, and neuralgic in character; but they shift, and are often accompanied by a staggering gait, sometimes by diplopia. Absence of the knee-jerk (the quadriceps extensor muscle at the same time responding freely to faradisation and blows), observed along with shifting neuralgic pains, is a strong indication of locomotor ataxy. The pains of syphilis in its second stage may be distinguished by the presence of fever, usually also of a rash, and by the fact that they affect many parts at once.

PROGNOSIS.—Youth, the absence of a strongly marked history of hereditary neurosis, the fact that neuralgia has followed exposures to unusual strain, violence, severe weather, or transient defects of nutrition, and that its attacks are influenced readily by treatment, afford a favourable prognosis. The onset of the disease after middle life, and its concurrence with signs of arterial degeneration, are

unfavourable as regards cure. Neuralgia of itself can scarcely be said to affect the duration of life. On the whole, neuralgia of the fifth nerve is the most persistent.

TREATMENT.—For success in treatment it is necessary that the basis upon which the neuralgia rests should be discovered. In patients suffering from malnutrition the diet should be ample and nutritious, and should include a fair amount of the fatty element, in the form of cod-liver oil, butter, or cream. A little stimulant may sometimes be necessary—enough to promote primary digestion; but no attempt should be made to relieve pain by its direct agency.

Where rheumatism is suspected as a cause of the neuralgia it should be treated by salicylate of sodium in twenty-grain doses three or four times a day. Two or three grains of iodide of potassium with fifteen of bicarbonate of sodium, taken every four hours, will often remove neuralgic pain connected with rheumatism. When malaria is suspected, it is well to follow up this treatment by quinine in doses of from five to ten or fifteen grains twice a day. A mercurial purgative may be usefully combined with a dose of quinine. If there be syphilis, iodide of potassium in ten-grain doses three times a day must be had recourse to; if gout, extract of colchicum may be given in one-grain doses twice daily, coupled with saline purgatives, especially Carlsbad natural salts. The salicylate of sodium is even more useful in gouty than in rheumatic cases. It should be given in doses of fifteen or twenty grains two or three times a day. Even where there is no history of malaria quinine will often be very useful, especially in neuralgia of the first division of the fifth (*see* TIC-DOULOUREUX). The liquor arsenicalis in doses of mij , increased cautiously to mviij or mx , and the tincture of steel, in doses of mxxx , largely diluted with water, may sometimes be used with advantage; and the latter will occasionally succeed even when there are no ordinary signs of chlorosis. As anemia may exist with a well-coloured face, the state of the gums and inner surface of the lower eyelid should be examined for undue pallor. Strychnine, in mij to mv doses of the solution three or four times daily, is especially useful in gastralgia; and belladonna, in $\frac{1}{4}$ gr. doses of the extract or mx doses of the tincture, in neuralgia of the pelvic viscera. Seclusion from irritation of various kinds—movement, cold, noise, dazzling light, worry—should be carefully maintained in cases of trigeminal neuralgia. All sources of peripheral irritation, of which decayed teeth, foreign bodies under the skin, intestinal worms, and imperfectly fitting boots are examples, should be carefully searched for, and where practicable removed. If lead be suspected, the drinking-water should be tested, and if the mineral be found iodide of potassium may be administered. Removal from imperfectly ventilated rooms, or from exposure to noxious gases, is essential. A warm, dry climate, such as Egypt or Algeria, will often cure when all other remedies have failed. For immediate relief in cases of extreme severity which resist other treatment, morphine may be injected hypodermically, either near the seat of pain, or in an indifferent part of the body. It is best used pretty freely diluted, mij of a solution of acetate of morphine, 1 to 30, being commenced with, and repeated, if necessary, when the pain returns. This dose may be gradually increased to one of mxv , but an effort

should be made to do with as little as possible and to avoid narcotic effects. The greatest care must be taken to avoid establishing a morphine-habit (p. 611). The following pill is often useful: R Quinina Sulphatis gr. j , Ferri Tartarati gr. ij , Morphinae Acetatis gr. $\frac{1}{12}$; repeated every hour or two when the onset is expected.

In all forms of neuralgia it is necessary to pay attention to the action of the bowels. In some cases considerable relief may be obtained by the use of small blisters (size of a florin), applied in the neighbourhood of the principal focus of pain, one following another at intervals of two days, not on but near the already blistered surface. The continuous current, derived from a sufficient number of cells of a battery to cause a characteristic feeling of burning, may be so applied that the affected nerve is as completely as possible included in the voltaic circuit. Sponges, or large leather-covered metallic disc-electrodes, moistened with warm salt water, should convey the current, and be kept firmly pressed upon the skin for about ten minutes; or, while one is stationary, the other may be slid along so as to linger in turn upon each focus of pain. To avoid shock the circuit should not be broken by the lifting of an electrode till the battery is 'let down' to zero. If relief be afforded, the application may be repeated many times a day, at intervals of a few minutes or hours. No notice need be taken of the position of the poles (+ and -), the object of the proceeding being simply to alter the electric tension of the tissues which are made to form part of the circuit. The method is often disappointing in its results, but sometimes gives a good deal of palliation.

In rare instances, but especially in ovarian neuralgia, the hypodermic injection of atropine ($\frac{1}{120}$ gr. to $\frac{1}{60}$ gr. of the sulphate) may prove serviceable. Where there is great restlessness and irritability of the nervous system, bromide of potassium in thirty-grain doses two or three times a day should be used. Relief, in slight cases of neuralgia, is obtained by applying to the skin by means of lint such liniments as the following: R Chloroformi zss , Tincturae Opii zss , Linimenti Belladonnae ad zij ; or R Spiritus Ammonia Aromatici, Aetheris, Tincturae Opii, Spiritus Vini Rectificati aa zj . Aconite and veratrine numb the sensory nerves, but they are uncertain remedies and very apt to cause irritation. Camphor-chloral with or without a little menthol may be applied with a camel's hair brush.

Phenazone in doses of five grains every half-hour, or from ten to twenty grains every four hours, is often very useful in neuralgia. An injection of mij of the *Injectio Cocaina Hypodermica* at the seat of pain will scarcely ever fail to produce at least temporary relief. The liability of the use of cocaine to induce a habit must, however, be carefully remembered (*see* HABITS). Phenacetin in doses of ten grains in cachets will frequently be of service. Exalgin may also be tried in doses of from two to four grains. The extract of cannabis indica, in doses of $\frac{1}{4}$ gr. frequently repeated, will sometimes produce great assuagement of suffering.

In unusually severe cases, which have lasted over years, a portion of the nerve may be excised; or, what is better, the nerve, which has been exposed by an incision, may be lifted from its bed and so firmly pulled upon as to be stretched, and then a portion excised (*see* NERVES, Diseases of). Very satisfactory results have sometimes followed this

procedure. Some time after the cure of a neuralgia there may be threatenings of a revival (dull heaviness, with tenderness of the part) following great fatigue or worry, but not immediately amounting to anything. Sleep is the best remedy for this condition, and this, if necessary, may be aided by giving ten grains of chloral hydrate.

For the treatment of coccygodynia see COCCYGO-DYNIA. T. BUZZARD.

NEURASTHENIA (νεῦρον, nerve; ἄ priv. ; and σθένος, strength).

DEFINITION.—A term used to describe a peculiar form of disease, sometimes spoken of as 'nervous exhaustion.' The name has, and with good reason, been objected to on account of its associations, and yet no better one has been proposed. Provisionally, therefore, since some name is essential, this must be used until a better is suggested.

SYMPTOMS.—The symptoms are protean, and vary so much in different cases that no accurate description of them can be given. They are very different, in the majority of cases, from those of 'hysteria' as it is generally understood, although no doubt 'hysterical' symptoms often co-exist. Many of the cases occur in clever, emotional, but not fanciful women, who would give all they possess to be well, and heartily long for good health, if they only knew how to obtain it; and in such cases the disease is as far removed as possible from the condition known as 'hysterical.'

In a large proportion of cases the origin of the illness can be distinctly traced to some cause injuriously affecting the nervous system, such as the loss of a near relative, monetary reverses, disappointments in love, or overstrain—of late so common in the modern system of high-class education in women. In the cases, comparatively rare, but still occurring from time to time in men, a similar origin from the vexations and strains of business affairs is often observed.

The disease is not, as a rule, suddenly established, but is the gradual outcome of deteriorated health. No distinctive or invariable symptom can be mentioned, but eventually there is a continuous inability for any exertion, a constant feeling of weariness and fatigue, until at last all effort is given up, and the patient gradually lapses into a bedridden or sofa-ridden invalid.

The appetite fails, all sorts of vague dyspeptic discomforts—flatulence, constipation, and the like—develop; and general, often excessive, emaciation is a common condition. There is, however, a well-marked, although less common, class of case, in which, along with all the symptoms of general weakness above referred to, there is a deposit of much unwholesome fat in the subcutaneous tissues, giving the patient a bloated, anemic, and very unhealthy appearance. The urine is pale, of low specific gravity, loaded with phosphates, with a diminished amount of urea, and sometimes a slight trace of albumen. Other vague nervous symptoms are present, especially sleeplessness, and various vaso-motor disturbances, such as palpitation and the like. Mental and emotional symptoms are pretty sure to be developed sooner or later, and are generally fostered by the use of drugs, constant fruitless attempts at cure, the habitual resort to chloral hydrate and other sedatives, and above all by the well-meant but often highly injudicious attentions of over-anxious relatives, nurses,

and, it must be added, doctors, which are rarely wanting.

Closely allied to this form of illness, and more properly termed hysterical, are a most important class of cases, in which there is a distinct imitation of real disease. Among these may be mentioned the so-called 'hysterical aepsia' of young girls, associated with most marked emaciation, loathing of food, and a strange unrest, leading to exhaustion of the ill-nourished muscles, or various forms of mimetic disease, such as paresis of the limbs, actual hysterical paralysis, hysterical vomiting, and the like. These, however, it is beyond the province of this article to dwell upon (see HYSTERIA). If the history of such cases be studied, it will be found that they show a lamentable record of fruitless attempts at cure, and in spite of all they have gone steadily down-hill.

TREATMENT.—To Weir Mitchell of Philadelphia undoubtedly belongs the merit of systematising a method of dealing with such cases, based on a common-sense appreciation of their causes, which renders them no longer an *opprobrium medicince*, but makes their recovery as nearly certain as anything medical can be, provided only that the cases are properly selected, and the treatment is intelligently and thoroughly carried out. This 'Weir-Mitchell' treatment is a systematised plan by which the weakened body is placed in thorough condition, by means of continuous rest, enforced feeding, and regular muscular waste produced by massage, which enables food to be taken and assimilated.

The essentials of this method are:—

1. Complete rest, the patient being placed in bed, and kept there during treatment; and it should be a *sine qua non* that this rest should not be in the patient's own house, but in a medical home or in lodgings, the friends and relatives, whose influence is often most injurious, being strictly excluded.

2. Regular muscular exercise to produce tissue-waste, by means of massage of the whole body, at first for ten minutes or a quarter of an hour twice daily, soon increased to an hour or an hour and a half. The influence of this is often misunderstood, and this treatment is frequently erroneously talked of as a 'massage treatment.' It should be borne in mind that massage is nothing more than a remedial agent, used for a specific purpose; that it is not the most important part of the cure; and that, used alone, and without enforced rest and over-feeding, as is unfortunately so often done, it cannot possibly be productive of any real good.

3. Feeding is the *most essential* part of the treatment. At first the patient should be placed on milk alone, about five ounces every three hour. Within a few days this is increased to ten ounces, so that at least two quarts are taken in twenty-four hours. Then, by degrees, solid food is added, so that within a fortnight the patient should be taking three large mixed solid meals daily, in addition to the milk, and often a cup of strong soup, with two teaspoonfuls of beef peptonoids added, twice daily as well. This exaggerated diet is continued for six weeks or two months, when it is gradually lessened, the massage also being discontinued, and the patient allowed to get up. In an average case the patient should gain from fourteen to twenty-three pounds during this time. It is strange to see how, with returning health, all invalid habits are lost, sleep becomes regular without drugs, the bowels cease to require assistance, and the whole appearance,

and apparently even the nature, of the patient is altered.

At the end of the treatment, in most cases, it is advisable that the patient should go for a change, either on a sea voyage or abroad, so as to complete the cure. At any rate, she should not return to her family until her health is re-established. The essential point to remember is that no half-measures should be permitted: if this treatment is not carried out thoroughly and completely, it had much better not be tried at all.

W. S. PLAYFAIR.

NEURITIS (*νεῦρον*, a nerve).—SYNON.: Periphereal Neuritis; Perineuritis; Interstitial Neuritis; Fr. *Névrite*; Ger. *Nerveneitzündung*.

DEFINITION.—Inflammation of a nerve, or of the fibrous sheath of a nerve.

ÆTIOLOGY AND PATHOLOGY.—This process occurs sometimes as an idiopathic change, the origin of which is altogether obscure, as where it implicates some of the intercostal or other spinal nerves, and is then often associated with an eruption of *herpes zoster* in related regions of the skin. At other times, as in some of the cases when it attacks the facial especially, or the sciatic nerve, neuritis seems to be set up as a result of local exposure to cold (see FACIAL PARALYSIS; and SCIATICA). Such forms of neuritis as these are commonly spoken of as 'rheumatic inflammations' of the respective nerves. Sometimes this appellation may be distinctly justified; but whether such changes have necessarily to do either with rheumatism or with a rheumatic predisposition seems, in many other cases, fully open to doubt.

Contusions or traumatic causes of various kinds may also set up inflammation in nerves. At other times a neuritis may be initiated in, and spread along, nerves leading from some wound or sloughing sore. This latter condition of things has been found to exist in some cases of traumatic tetanus (see TETANUS). Or an inflammation already existing may spread from some contiguous structure to adjacent nerves, as when cranial or spinal nerve-roots become involved in the course of a meningitis.

The apparently idiopathic forms of neuritis, as well as those following upon exposure to cold, are specially prone to show themselves when certain predisposing causes have been for some time in operation. Among these some of the best known and most frequently operative are the gouty diathesis, the syphilitic cachexia, and the presence of diabetes; in each of which neuritis in some form or other is of common occurrence. Other more specific predisposing causes of neuritis exist in the presence of leprosy, of epidemic influenza, or of poisoning by lead or arsenic. Many of the toxic causes, in fact, which are most effective in the production of a multiple symmetrical neuritis of parenchymatous type (see NEURITIS, MULTIPLE) are also capable of inducing a localised neuritis of peripheral or interstitial type, such as we are now considering—and this may vary much in intensity and also in its degree of acuteness or chronicity.

ANATOMICAL CHARACTERS.—Strictly speaking, we have mostly to do in this pathological state with inflammation of the sheath of the nerve, or of its interstitial tissues, rather than with changes in the nerve-fibres themselves. It is possible, of course,

that the nerve-fibres in this condition may undergo some distinctive pathological changes; but what is at present known is, that the neurilemma, or connective-tissue sheath of the nerve (including its minute prolongations between and around separate bundles of nerve-fibrils), becomes much more hyperæmic than natural, and that on microscopical examination there is to be found, in addition to the increased vascularity, a multiplication of new tissue-elements and the presence of migrated leucocytes. These changes may cause considerable swelling of the nerve-sheath and of its prolongations, and thus may produce either mere irritation or more or less compression of the nerve-tubules, according to the amount of new elements which accumulate in or are produced within the nerve-sheath. So that degenerative or sub-inflammatory changes in the nerve-fibres may, at least, often be found co-existing as secondary or induced phenomena.

All such changes may be localised to particular regions, or they may extend more or less diffusely along the whole length of a nerve.

SYMPTOMS.—The symptoms of neuritis will necessarily vary much according to the functions with which the affected nerve is concerned. There may be impairment of special or common sensibility, or pain may exist (referred to the peripheral distribution of the nerve), with more or less distinct tenderness along its course or at its point of emergence from some bony canal. In these cases the pain is generally paroxysmal and neuralgic in character, while the skin is hyperæsthetic, and perhaps shows some vaso-motor or trophic changes. All these phenomena are well illustrated in diseases of the trigeminus (see TRIFACIAL NERVE, Diseases of), and therefore need not be dwelt upon further here. Where a strictly motor nerve is implicated, there may be twitchings of the muscles to which it is distributed, followed by more or less distinct paralysis, and subsequently marked wasting of the affected muscles—conditions which are well exemplified in inflammations of the facial nerve (see FACIAL PARALYSIS). In the case of a mixed nerve being involved, both kinds of symptoms present themselves—that is, more or less severe pains and tenderness, with trophic symptoms, and distinct paresis or paralysis, with subsequent atrophy of the muscles to which the nerve is distributed. A detailed consideration of such phenomena would be needless here, as they are set forth in relation to inflammation in the sciatic nerve, under the article SCIATICA; and also because all such symptoms and changes are likewise considered under the article NEURITIS, MULTIPLE.

There is, undoubtedly, an intimate relationship in many cases between different forms of neuritis and neuralgia affecting similar sites; the reader may, therefore, be further referred to the article NEURALGIA for additional information.

TREATMENT.—The treatment of neuritis is both general and local. The general treatment is of especial importance in cases where the condition seems attributable to the influence of syphilis, and then the administration of small doses of perchloride of mercury, in combination with large doses of iodide of potassium, will often produce marvellously beneficial results. Smaller doses of iodide of potassium alone, or with colchicum, are to be given in other cases, in which rheumatism or gout may seem to be one of the factors in exciting the nerve-inflammation. But in these cases, and also in those

which are simple results of exposure to cold, the cure may be often expedited, and the patient also temporarily relieved, by local treatment, such as the application of a few leeches (especially in the early stages), hot fomentations, or small flying blisters.

During the course of the treatment special symptoms may become all-important. Thus, pain may become so agonising as imperatively to demand measures for its relief; and, where paralysis is one of the symptoms, galvanism or massage (or perhaps both) must be employed daily, or two or three times a week, in order to prevent as much as possible the muscles from degenerating while the pathological condition in the nerve is being cured—that is, in cases in which a cure is possible. All these indications, however, will be found more fully considered under the articles SCIATICA; and NEURITIS, MULTIPLE. H. CHARLTON BASTIAN.

NEURITIS, MULTIPLE.—SYNON.: Polyneuritis; Peripheral Neuritis; Fr. *Paralysies Périphériques*; Ger. *Multiplex Neuritis*; *Neuritis Acuta Progressiva*.

DEFINITION.—A nervous affection characterised by various motor, sensory, and trophic symptoms; dependent upon disease occurring simultaneously, or in rapid succession, in the peripheral terminations of nerves in various parts of the body, under the influence of extrinsic or intrinsically derived toxic agents of one or other kind.

ANATOMICAL CHARACTERS.—The morbid changes that occur in the nerves in this disease are met with principally at their finer terminations, or, it may be, even exclusively there. Where the larger branches of the nerves are also involved, the intensity of the process generally diminishes as we recede from the periphery. A second peculiarity is that the changes are most frequently symmetrical on the two sides of the body, whether the nerves affected be in the limbs, where they are by far the most frequently involved, or in other parts. A third peculiarity is that the inflammatory or degenerative changes are found to occur essentially in the nerve-fibres themselves, rather than in their sheaths or interstitial tissues; or, in other words, that the inflammatory changes are in the main parenchymatous, rather than interstitial as they are in simple neuritis. Of course these two kinds of change do not occur singly in either case, but in multiple neuritis it seems plain that the parenchymatous changes are distinctly in excess, and they are believed also to be primary rather than secondary degenerative changes due to strangulation of the nerve-fibres higher up, as some have imagined. Though primary parenchymatous changes may be the rule, we may still admit the occurrence also of secondary degenerative changes in the nerve-fibres.

The naked-eye alterations in the appearance of the nerves may not be great. Their extent depends in part upon the amount of co-existing inflammation in their connective-tissue envelopes, and in part also upon the severity and duration of the inflammatory process in the nerve as a whole. But even where they are not notably swollen and hyperæmic, the nerves may be deficient in their proper lustre, and irregular in their contour, owing to accumulations of fat derived from degenerated myelin; or, in later stages still, they may be wasted and reduced to little more than mere connective-tissue strands. It may often happen, however, that no very appreciable changes are to be detected by

the naked eye, and that, in order to establish the existence of multiple neuritis, the finer branches of the nerves have to be dissected out and submitted to careful microscopical examination.

Where changes exist in the sheath and interstitial tissues of the nerves, they are such as have already been described in the article NEURITIS, consisting in the main of increased vascularity, some amount of exudation of serum, migration of leucocytes, and multiplication of nuclei in the sheath of Schwann and elsewhere. The distinctive changes that occur in multiple neuritis are, however, those which take place in the nerve-fibres themselves. These agree in almost all respects with the changes that occur in the 'secondary degeneration' of a nerve on the distal side of a section or other severe injury. The myelin first becomes cloudy and granular, and then undergoes segmentation—first into large and subsequently into smaller and smaller masses, until at last there is left only a number of fatty-looking globules and particles surrounding the swollen and altered axis-cylinder. As this process advances the sheath of the nerve gives way here and there; surrounding cells swell, and, taking up the fatty particles, become converted into 'granulation-corpuscles,' while ultimately the axis-cylinder may be more or less completely destroyed.

However extreme the changes in the nerves may be, it is now certain that, in periods of from six to twelve months or more, complete regeneration may take place, just as it has been observed to occur in experimental lesions in the lower animals. New axis-cylinders become formed in continuity with the old, and these subsequently become surrounded with sheaths of myelin. Thus it is that the prognosis in a given set of symptoms caused by peripheral neuritis is so much better than it would be if the symptoms had been dependent upon similarly severe lesions occurring in the spinal cord itself.

Atrophic degeneration of muscles, in relation with the affected nerve, progresses *pari passu* with the changes of the latter. The muscle-fibres waste from the occurrence of fatty and granular degeneration, while the nuclei of their sheaths multiply, and hyperplasia of tissue-elements also takes place in the intervening connective tissue.

Occasionally in some of the worst cases, in which death has occurred, it has been established that small changes of different kinds occur also in the spinal cord. Such changes have been found more especially in the cases of multiple neuritis caused by alcohol, lead, arsenic, diphtheria, and chill; but they may well occur also where multiple neuritis follows in the wake of other causes. The changes met with here for the most part consisted of atrophic conditions in the great ganglion-cells of the anterior cornua, together with some amount of over-growth in the surrounding neuroglia.

In addition to these more or less essential changes other morbid conditions might be expected in internal organs, varying widely in their nature in different cases, in accordance with the varying conditions under the influence of which the multiple neuritis has been established; that is, we may meet with visceral changes due to previous alcoholism, to malarial poisoning, or to some antecedent acute specific disease, as the case may be.

ÆTIOLOGY AND PATHOLOGY.—The best-known forms of this disease are undoubtedly due to the action of poisons circulating in the blood upon the peripheral terminations of nerves in different parts

of the body, and especially upon those of the extremities. The evidence of this mode of causation is so strong for so many forms of the affection that it is now pretty legitimately conjectured to be, in one way or another, applicable to all of them—that they are in fact all toxic forms of paralysis, though capable of being arranged into different groups according to the nature, or the mode of production, of the toxic agencies in question. From this point of view the best-attested causes of multiple neuritis may be roughly classified in the following manner:—

A. *Poisons of Extrinsic Origin.*—Alcohol; Arsenic; Bisulphide of Carbon; Lead.

B. *Poisons evolved by Microbes associated with various Infective or Endemic Diseases.*—Diphtheria; Variola; Typhoid Fever; Typhus Fever; Measles; Beriberi; Septicæmia; Malaria; Influenza; Syphilis; Leprosy; Tuberculosis.

C. *Poisons evolved during Metabolic Processes occurring in some of the Organs and Tissues of the Body itself.*—Chill; Excessive Muscular Exercise; Diabetes Mellitus; Gout; Cachectic states; Idiopathic or 'Spontaneous' Cases.

The cases belonging to (A) the first category supply, of course, the clearest evidence that multiple neuritis is due to the presence of poisonous substances circulating with the blood, and thus exerting an irritative influence on the peripheral nerves.

The diseases comprised in (B) the second category, in the course of which, or as sequels of which, multiple neuritis has been found to occur more or less frequently, are all of them associated with the growth and multiplication of micro-organisms either in the blood or in some parts of the body. Under such circumstances it is well known that alkaloidal and other substances of a poisonous nature (toxins) are more or less abundantly produced, as excreted products, during the life-activity of the micro-organisms, which substances, finding their way into the blood, may act upon the peripheral nerves in much the same manner that alcohol or arsenic does. It is well known that such effects do not occur in all cases, but only in a comparatively small proportion of the cases of each of these diseases. We must, therefore, suppose that, in the cases in which multiple neuritis is produced, there has either been some slight variation in the nature of the poisons finding their way into the blood, or else that the ordinary poisons associated with the several diseases are aided, in such individuals, by the co-existence of one or more intrinsic favouring conditions.

In regard to the third category (C) of cases, in two of them at least it is known that the blood is especially apt to be altered in composition, and to contain products which may exercise an irritative influence upon the peripheral nerves in some parts of the body. The excess of uric acid in the blood may operate in this way in gout; while in diabetes the irritative effects upon the nerves are not supposed to be due to the presence of an excess of sugar in the blood (since the frequency of the association of the disease with neuritis bears no regular relation to the amount of sugar contained therein), but rather to the presence in the blood of some acid or ethereal products (derivatives of β -oxybutyric acid), such as are known to occur at times in association with diabetes mellitus. It seems perfectly certain, also, that some of the cases of multiple neuritis are set up after exposure to chill and cold; just as, in other subjects, acute spinal paralysis may be engendered under similar conditions. These are the cases of

so-called 'rheumatic' origin; and it is conjectured that in them some poisonous product is formed within the system, as a result of the chill, which, according to individual proclivity or the nature of the products engendered, excites either multiple neuritis or acute spinal paralysis, or it may be both; just as, under other individual conditions, the malady excited is an acute articular affection, or an acute inflammation of some other internal organ. Lastly, in certain cachectic or anæmic states of the system there is a tendency to the occurrence of neuritis; and perhaps it is principally to this kind of causation or to the occurrence of slight exposure to cold that we may ascribe the so-called idiopathic or 'spontaneous' cases of multiple neuritis—that is, cases for which no very distinct cause of a toxæmic character can be assigned.

If we omit the aetiologically obscure cases last referred to, it will be seen that all the conditions under which multiple neuritis is prone to occur are states of the system in which poisons of one or other kind would be circulating with the blood; and such a mode of origin for the inflammatory condition of the nerves is rather confirmed by the fact of the remarkably symmetrical distribution of the neuritis that is so commonly met with in these cases, and to which reference has already been made.

We must not omit to mention, moreover, the fact of the relation supposed to exist between Raynaud's disease and peripheral neuritis. While referring to the article on that disease (see RAYNAUD'S DISEASE) for further information, it need only be said here that multiple neuritis may or may not show itself as an epiphenomenon rather than as an essential constituent of this remarkable morbid condition.

Then, again, it should be said that 'acute ascending paralysis' (Landry) has been held by some, and especially by the late Dr. Ross, to be one of the idiopathic forms of multiple neuritis. From the clinical point of view there is undoubtedly much to be said in support of this doctrine, but the proof of this position has yet to be established. See SPINAL CORD, Special Diseases of.

Multiple neuritis occurs with all degrees of severity, not only at different times under the operation of the same kind of cause, but also very notably under the influence of the different causes that have been above enumerated. The latter difference is so striking that the several causes above referred to may, from the point of view of the average intensity of the multiple neuritis which they engender, be divided into two classes, as follows:—

Causes of more Intense Forms of Multiple Neuritis. Beriberi; Alcohol; Arsenic; Chill; Diphtheria; Variola; Excessive Muscular Exercise; Typhus Fever; Typhoid Fever; Measles; Influenza.

Causes of Slighter Forms of Multiple Neuritis. Bisulphide of Carbon; Lead; Malaria; Septicæmia; Syphilis; Leprosy; Diabetes Mellitus; Gout; Tuberculosis; Cachectic states.

The cases of multiple neuritis that occur under either of the first class of causes may be, and often are, well-developed typical forms of the malady; those, on the other hand, which occur from one or other of the second class of causes are much more habitually ill-developed and more or less localised forms of the affection, and in some of these cases (especially those associated with leprosy, syphilis, or gout) it is the sheath and interstitial tissues of the nerve, rather than the nerve-fibres themselves, which are most prone to be affected. In these

cases, also, the inflammation is often not limited to the peripheral twigs, but may involve the main trunks and the roots of the nerves. In all respects, indeed, there is in these cases often more the characters of a local neuritis than of the more general affection.

It should be borne in mind, again, that in many of the cases of multiple neuritis there may have been more than one cause in operation; thus, alcohol and anæmic conditions of the system, or syphilis, may co-operate with tuberculosis; chill or lead with alcohol; or local exposure to wet and cold may reinforce syphilis or gout in the production of some of the more localised forms of multiple neuritis. The recent widespread epidemic of peripheral neuritis in certain parts of the north of England, due to the presence of arsenic in one or other of the ingredients used in the manufacture of beer, has, however, shown that one of the most potent combinations for the production of this disease is a mixture of arsenic with alcohol.

In the more intense forms of multiple neuritis lesions may occur in the spinal cord as well as in the peripheral nerves. This is notably the case in some of the 'rheumatic' forms of the disease, and in some of the cases due to lead, diphtheria, or some other of the acute specific diseases.

Neither in the more intense nor in the more localised forms of the disease are we able definitely to bridge the gap which lies between our knowledge of the ætiology and that of the morbid anatomy of this affection—we are unable to say anything definite, that is, as to the exact pathogenesis of the changes in the peripheral terminations of the nerves or in the spinal cord. No light whatever is really thrown upon this obscure subject by the hypothesis that functional changes in spinal trophic centres first occur, which lead secondarily to the observed failure or perversion of nutrition in the peripheral nerves. It would only shift the difficulty farther back, even if this hypothesis explained (which it does not) the localisation of the changes in the nerves to their peripheral terminations. As it is, we can only suppose that the tissues affected, and the particular parts of them, are, by their individual constitution, especially prone to be irritated by the presence in the blood of the various poisons to which we have referred.

Multiple neuritis from one or other of the causes mentioned may occur at almost any age; but the disease is by far the most frequently met with some time between the twentieth and the fiftieth year.

Some separate description or mention must now be made of the different forms of multiple neuritis.

A. Cases due to Common Poisons.—*Multiple Neuritis due to Alcohol.*—This is the commonest of all the forms of multiple neuritis, and it is met with also much more frequently in women than in men. Spirit-drinking seems to be most prone to excite it, and especially when spirit is taken in small or moderate quantities continuously over long periods, and when at the same time there has been little exercise in the open air. While alcoholic neuritis is more common among women, delirium tremens is more frequent among men—differences which may be dependent partly upon sex, but perhaps more notably upon the different habits of the two sexes, especially in regard to extent of open-air exercise.

SYMPTOMS.—The onset of the affection is generally gradual, being often preceded for months or

weeks by gastric symptoms, insomnia, and rapid pulse, together with numbness and tingling, shooting pains, tremors, cramps, and some paresis of the limbs—especially of the lower limbs. Actual loss of power may then come abruptly at any time, at first in the feet and legs, later on in the thighs—though, often before they become involved, the hands and arms also show signs of paralysis, which is most marked in the extensors of the wrists. In many instances the paralysis may stop here; but in the more severe cases it gradually advances so as to involve the nerves supplying the trunk muscles, some of the cranial nerves, and at last perhaps the phrenic nerve.

The 'dropped wrists,' and the 'dropped feet,' as the patient lies in the recumbent position, are very characteristic of multiple neuritis; and the paralysis of the limbs is almost always of the flaccid type. The affected muscles speedily become flabby and much wasted. When in this condition they show a more or less modified electrical 'reaction of degeneration.' They usually cease to respond to faradism; and if they respond at all to galvanism, it is only to very strong currents, and that in a slow, sluggish manner, the reaction to A.C.C. being greater than that to C.C.C. In some exceptional cases, and in the early stages of the affection generally, the electrical reactions may be very little altered.

Various disturbances of sensibility cause the greatest distress to the patient. The limbs are often the seat of excruciating pains, the skin is more or less generally hyperæsthetic, and the muscles also in the affected parts are extremely tender, even to slight pressure. There is often, moreover, marked tenderness along the course of the nerves, so that the patient is apt to cry out when touched or moved even in the gentlest manner. In addition, various paræsthesiæ, such as tingling, numbness, and formication in the limbs, are mostly present. In the more severe cases these latter symptoms may disappear during the height of the malady, when anæsthesia becomes developed, but may be expected to return as recovery advances. With cutaneous anæsthesia of the limbs, often localised to the terminal portions or to the areas of particular nerves, there may also be more or less marked loss of muscular sense. Some of the special senses may also be affected, especially vision, leading to amblyopia and contraction of the field for colour-vision. Occasionally, also, inequality and slight contraction of the pupil has been met with, and very rarely optic neuritis. The cutaneous reflexes are often present, but may be lost where the anæsthesia is marked. The knee-jerks are commonly lost at an early stage of the affection; but occasionally, in exceptional cases, they are found to be retained, and even to be slightly exaggerated for a time.

In many of the slight cases of the disease a certain amount of inco-ordination as well as paralysis can be recognised; and in the cases in which the involvement of the muscular sense is more than usually marked, a slight ataxic condition is produced in both the arms and the legs, but especially in the latter. This, in combination with other symptoms present, such as the pains in the limbs, the loss of the knee-jerks, unsteadiness when the eyes are closed, and a peculiar high-stepping gait, causes the patient's condition to resemble more or less closely that met with in locomotor ataxy. Such cases are now spoken of *pseudo-tabes*; and, although

they may be met with in multiple neuritis from any other cause, they seem to be rather specially frequent in the form of the disease due to alcohol, though perhaps still more so when it is due to arsenic or to a combination of these toxic agents. The points which enable us to distinguish these forms from true tabes will be referred to later under the head of 'Diagnosis.'

Vaso-motor and trophic symptoms occur in some cases about the feet and hands, in the form of oedema, lividity, glossy skin, and more or less profuse sweating. Later on, the limbs are still further altered, especially in old neglected cases, by the occurrence of contractures of the fingers and of the calf-muscles, due to weakness of the extensors. Bed-sores are usually absent; and power over the sphincters of the bladder and rectum is commonly retained.

In the early stages of alcoholic neuritis there is another class of symptoms of great importance commonly present, namely, those of cerebral type. These are sometimes most marked, and of a very varied character. There may be loss of memory, loss of ability to concentrate the attention, together with illusions and hallucinations—especially towards evening and at night, when insomnia is often most obstinate and very exhausting to the patient. In some cases there may be distinct delirium continuing for days; and, even where this is not present, there is often a peculiarly active imagination, together with a sort of waking dream-like state. Thus, patients will give circumstantial details of imaginary events in which they have taken part, or of visits which they have paid within the last hour or so, when they have been quite incapable of even leaving their beds. In the course of a week or so, under proper treatment, such symptoms will gradually subside. The patient will then (or earlier where the more acute symptoms are absent) show distinct evidence of a lowered *morale*. Statements about their habits in regard to alcohol are almost always unreliable, often flagrantly untrue, and made even in the face of the strongest evidence to the contrary. We must look to the relatives or the associates of the patient if we are to obtain correct testimony in regard to this matter.

The course of the disease in alcoholic neuritis is pretty constant, though its duration is extremely variable, according to the degree of severity of the attack. After a slow or more abrupt onset the symptoms go on increasing up to a certain point; then there is a decline of the more urgent symptoms in a gradual fashion; after this the patient may remain in a more or less stationary condition for many months; finally, a period of slow improvement sets in, during which the tenderness of the muscles abates, and their nutrition and power improve, the anaesthesia diminishes, and with it there is a return of numbness and tingling in the hands and feet. The duration of the disease varies from two or three months to from one to two years.

Multiple Neuritis due to Bisulphide of Carbon.—Delpsch showed that the effects of this compound upon the system were somewhat similar to those of alcohol. The symptoms are principally met with in rubber-factory operatives. It appears that intense frontal headaches are common among workers in rubber, even though no further symptoms develop. As the intoxication proceeds, according to F. Peterson, 'giddiness and even actual drunkenness become manifest, the workpeople becoming excitable,

talkative, and hilarious.' Among later chronic manifestations are multiple paresis, due to a multiple neuritis, mental weakening and apathy, amblyopia, tinnitus, fornication, anaesthesia of the feet, muscular cramps, occasionally convulsions, at first increase of sexual appetite, later impotence in men and sterility in women. In the same communication Peterson records three cases of acute mania resulting from inhalation of the fumes from a mixture of bisulphide of carbon and chloride of sulphur. The poisonous effects from the use of these chemicals are now obviated to a considerable extent by maintaining a more thorough ventilation in rubber-factories. See OCCUPATION-DISEASES.

Multiple Neuritis due to Arsenic.—It has been long known, from experiments by Orfila, that in certain cases paraplegic conditions were induced occasionally after the taking of large doses of arsenic. Of late years it has been ascertained that the poisonous effects of arsenic are sometimes very similar to those produced by alcohol. The paralytic effects thus produced were previously ascribed to changes in the spinal cord; but it has now been ascertained that such changes are only occasional, and that the majority of the effects to which we are referring are due rather to peripheral neuritis. These effects occur sometimes, though only very rarely, after the patient has taken for a prolonged period small doses of arsenic, such doses at last giving rise to symptoms of acute poisoning. Then, after a variable interval—some days, or a week or two—the symptoms of peripheral neuritis begin to develop.

In other cases, however, such symptoms may set in a short time after acute poisoning by arsenic, when the drug has been taken in excess either accidentally or with suicidal intent. A typical case of this latter type has been recorded by H. Jolly. The patient had taken, with a view to suicide, a quantity of Schweinfurth Green. There was immediate vomiting, and for two days symptoms of gastritis. She remained very weak, and noticed, when she attempted to rise on the fifth day, some numbness of the feet. Then followed paræsthesiæ simultaneously in feet and hands, with a creeping sensation that was at times very painful. These symptoms continued during the next few weeks, and to them was soon added a more distinct weakness, especially of the lower extremities. After four weeks the patient was unable to walk alone; and when, in the following week, she was admitted into the hospital for nervous diseases, she could only walk when supported on both sides. There was also marked ataxy. The knee-jerks were lost on both sides, and there was great paresis in the legs, with specially impaired movement in the feet and toes. In six weeks the paralysis of the feet and toes was complete; there was atrophy of the muscles of the calves of the legs, and great disturbances of sensibility. The patient was insensible to slight touches, but felt stronger touches well; and there was pronounced hyperalgesia. The tips of the fingers were quite anaesthetic, and there were sharp pains in the hands and in some of the deeper parts of the forearm and arm. In the course of the following week the symptoms became somewhat worse, especially the pains. A feeling of coldness was also complained of in the right upper extremity, and there was profuse sweating in the palms of the hands. From about the twelfth week onwards a decided improvement began to take place in regard to both motor and sensory symptoms.

The superficial reflexes in arsenical polyneuritis are mostly preserved, while the knee-jerks are lost; the legs also are commonly more affected than the arms. There is much variation met with in the symptoms of individual cases, and in many of them distinct impairment or loss of muscular sense and ataxic symptoms are fairly well marked (pseudo-tabes). In almost all respects, in fact, the symptoms of the multiple neuritis due to arsenic are found to accord closely with the alcoholic form of the disease, with the very important exception that the head- or cephalic symptoms, with hallucinations and delirium, are generally absent, while more or less marked pigmentation of the skin is apt to show itself in some persons.

Our knowledge of the symptoms due to chronic poisoning by arsenic has, unhappily, been much extended of late owing to the occurrence of a widespread epidemic of multiple neuritis in certain parts of the north of England caused by the presence of arsenic in different ingredients used in the manufacture of beer. This poisoning has been going on to some extent for several years, but it attained its maximum in the latter part of 1900, when its cause was first pointed out by Ernest Reynolds of Manchester. To him as well as to Judson Bury we are principally indebted for a considerable increase in our knowledge of the symptomatology of the multiple neuritis due to arsenic—or rather to arsenic and alcohol in combination, for there is little room for doubt that the activity of arsenic in the production of this malady has been notably enhanced by the fact of its having been taken in association with alcohol in the form of beer. We are led to this conclusion from the fact that arsenic is taken by many epileptics in association with bromides over long periods and in amounts quite equal to those imbibed by even the most intemperate of the beer-drinkers who have suffered from multiple neuritis in the north, and yet without the production of any such symptoms. It is possible, of course, that bromides may to some extent diminish the poisonous effects of arsenic (though they do not always prevent pigmentation of the skin), but it seems clear that its poisonous influence is heightened by being taken in association with alcohol.

The mixed effects of these two poisons as met with in the recent epidemic have often shown themselves in the following order: (1) digestive symptoms; (2) laryngeal catarrh, bronchitis, and acute skin-affections; (3) disturbances of sensibility; (4) motor paralysis and chronic skin-affections.

The face was often noticed to be puffy, especially about the eyes; the eyes were suffused and watery; and the face often showed some amount of pigmentation. Pigmentation of the skin also in various parts of the body, especially where subject to pressure from clothing, and in special regions, having a patchy or punctiform arrangement, was found to be very common. Erythematous eruptions, with much itching; herpes zoster; and keratosis of the hands and feet; as well as erythromelalgia (p. 491) of the same parts, were likewise frequently met with.

Mental symptoms were commonly slight. Sensory symptoms were rather more marked, and pseudo-tabes more frequent, than with the simple alcoholic form of the disease. Tenderness of the muscles to deep pressure was commonly very marked. In some of the cases there was notable failure of the heart's action, with the usual oedema of feet and legs, and pulse of low tension.

Multiple Neuritis due to Lead.—The effects of the multiple neuritis caused by lead are still more localised than those due to arsenic alone. There is not only the absence of the characteristic group of head-symptoms, but still further a common limitation of the neuritis to the motor nerves, and especially to those of the upper extremity. The ordinary effects of peripheral neuritis due to lead will be found described under LEAD, POISONING BY. The symptoms closely resemble those due to spinal-cord disease, to which, indeed, some of the effects are often partly attributable. For, though peripheral neuritis is the lesion commonly met with, it happens here even more frequently than with other forms of multiple neuritis that lesions in the anterior cornua of the spinal cord are also produced; and it is to these latter lesions that the symptoms are occasionally, in part at least, attributable.

But although it is the rule for the effects of the multiple neuritis due to lead to be thus limited to a part of the field of distribution of the motor nerves of the upper extremities, it is not invariably so. Thus, muscles about the shoulder and arm (especially the deltoid and brachialis anticus) may be affected as well as those of the forearm; and occasionally even some of the leg-muscles, especially the long extensors of the toes and the peronei muscles. Again, in some cases of multiple neuritis due to lead there have been distinct disturbances of sensibility, that is, more or less severe pains, some tenderness of affected muscles, and perhaps also along the affected nerves, together with tingling and numbness in their field of distribution. In certain other cases of multiple neuritis due to lead we may have the association of a more or less marked hemiplegic condition, in which hemi-anæsthesia is well developed. This latter condition is generally of more or less brief duration, and is supposed to be due to some functional defect in the brain, analogous to that occurring in hysteria. In this connection it must not be forgotten, moreover, that intense double optic neuritis and also convulsions may occur in the course of lead-poisoning.

B. Cases due to Microbic Poisons.—*Multiple Neuritis associated with, or sequential to, certain Infective or Endemic Diseases.*—The cases belonging to this category are those forms of multiple neuritis which are associated with, or, as is by far the most common, are sequential to, one or other of the following morbid conditions, namely, diphtheria, variola, typhoid fever, typhus fever, measles, beriberi, septicæmia, malaria, influenza, tuberculosis, syphilis, or leprosy.

Almost all these varieties of the disease were formerly ascribed to morbid conditions, either functional or structural, of the spinal cord. It is true, indeed, that functional diseases as well as certain structural affections of the spinal cord, in the form of indurations (scleroses), softening, hæmorrhages, together with limited inflammations or atrophic conditions of the anterior cornua, are especially apt to occur occasionally as sequels of one or other of these diseases. But since the clinical characteristics of polyneuritis have been more commonly appreciated, it has been recognised that these particular groups of symptoms occur not infrequently as sequels of one or other of the diseases above mentioned—the truth of this diagnosis having, moreover, been often confirmed by necropsies which have demonstrated the presence of

multiple neuritis, mostly alone, but more rarely with some co-existing changes in the spinal cord.

The severity of the disease varies very much indeed in this category of cases. Sometimes it presents itself as an acute progressive affection involving all the limbs, and subsequently the nerves supplying the trunk muscles and those of the face and eyes, together with a well-marked association of sensory symptoms of the usually varied character. At other times, and especially after diphtheria, the motor paralysis is less marked, and symptoms of a more ataxic type present themselves (pseudo-tabes); while, in other cases still, we may have to do with a localised rather than with a more generalised neuritis. The forms of multiple neuritis associated with diphtheria are apt to occur, on different occasions, in each of these types; the severe general cases, however, in which death may occur from paralysis of the diaphragm are rare and exceptional; while localised forms of paralysis limited to the palate, and associated with slight parætic or ataxic conditions, are by far the most common (see DIPHTHERIA). On the other hand, in beriberi we have to do much more frequently with a generalised form of neuritis, in which speedy death occurs not at all rarely (see BERIBERI). In other of these diseases, such as variola, typhus and typhoid fevers, measles, septicæmia, and malaria, polyneuritis supervenes rarely; but in each of these affections it may appear in a well-developed form.

Again, it seems clear that in influenza, tuberculosis, syphilis, and leprosy, in the absence of other co-operating causes, the neuritis that occurs is apt to present itself in a more or less localised form; and, in the case of syphilis and leprosy more especially, the neuritis is principally of the peripheral and interstitial type. These forms of the disease are thus, perhaps, rather more closely allied to ordinary neuritis than to multiple neuritis. Still, it seems probable that both syphilis and tuberculosis may decidedly favour the action of other more potent causes, such as alcohol or chill, in the production of well-marked multiple neuritis.

The only one of these forms of multiple neuritis to which any special reference need be made is that which may be associated with malarial poisoning. Sometimes this, either alone or aided by other causes, such as exposure to cold or excess of alcohol, induces ordinary forms of multiple neuritis of medium severity, affecting the arms and legs, but especially the latter. At other times, however, malaria gives rise to what, since the description given by Romberg, has been known as 'intermittent paraplegia.' This remarkable affection has been found to occur only in patients suffering from malarial poisoning. It is characterised by the sudden onset of paralysis in the lower extremities, which may or may not be accompanied by some anæsthesia and by paralysis of the sphincters. After some hours the paralysis disappears, perhaps accompanied by the appearance of a critical sweat, and reappears in a more or less regular manner, according as the attack assumes a quotidian, tertian, or quartan type. This affection has been found to be very amenable to treatment by quinine. Cases have been recorded by excellent observers, such as Hartwig, Erb, and Westphal, and it is now generally believed that, instead of being due to altered functional conditions of the spinal cord (which was the interpretation formerly given), this remarkable transitory and recurrent form of paralysis is depen-

dent rather upon a peripheral neuritis occasioned by some poison formed during the course of a malarial attack.

C. Cases due to Autogenetic Poisons.—

Multiple Neuritis sequential to Chill.—The disease from this cause not infrequently supervenes in an acute fashion, and may at the onset be associated with distinct febrile symptoms, the temperature rising to some point between 101° and 103° . There may also be pains in the back, limbs, and joints, so as to give rise to the suspicion, perhaps, of a commencing attack of rheumatic fever. To such symptoms may be added headache and anorexia, together with tingling and numbness in the fingers and toes, and more or less tenderness over the principal nerves in the limbs. The legs and arms subsequently show an increasing paralysis, commonly beginning first in the legs. Then paralysis may spread to the trunk-muscles, and to those of the tongue, palate, and larynx (so as to impair deglutition and articulation), even if it does not extend to other cranial or to the phrenic nerves. The knee-jerks are speedily lost, the paralysed muscles soon waste, and their electrical reactions become altered in the usual manner. At the same time various sensory disturbances become developed, such as tenderness of the muscles and hyperæsthesia of the skin (soon to be followed by, or intermixed with, areas of anæsthesia); while glossy skin, increased sweating, and other trophic symptoms may also make their appearance.

These cases subsequently pursue much the same course as severe cases of alcoholic neuritis. Death may occur in the course of a week or ten days from respiratory or cardiac paralysis; or, all fever having subsided, the patient may remain in a tolerably stationary condition for several weeks, before the usual slow improvement begins to set in.

In other instances the multiple neuritis following chill may be less acute and less severe, and the amount of sensory symptoms is very variable. When the latter are very slight, such cases are apt to be mistaken for those of acute spinal paralysis; and when they are more severe (especially where there is much involvement of the muscular sense) the symptoms are more of an ataxic order, so that the case may present itself as a form of pseudo-tabes.

Multiple Neuritis sequential to Excessive Muscular Exercise.—Although typical cases have been recorded, verified by necropsy, seemingly referable to this cause, they are nevertheless of extremely rare occurrence. So far as the form and course of this variety of multiple neuritis are concerned, it seems to agree most closely with that induced by chill, and different cases are liable to individual variation in much the same manner.

Multiple Neuritis associated with Diabetes, Gout, or with Cachectic states.—Each of these varieties of multiple neuritis is liable, though only very rarely, to occur as a more or less generalised affection. As a rule, however, it is much more common for the neuritis when associated with either of these affections, and when other co-operating causes are absent, to occur in a limited form, affecting only some one or two nerves—the inflammation that is established being also peripheral and interstitial rather than parenchymatous in type. Gout has been long known as a common predisposing and even exciting cause of ordinary interstitial neuritis.

Multiple Neuritis of 'Spontaneous' Origin.—Every now and then ordinary attacks of multiple neuritis, sometimes severe and sometimes slight, make their appearance without its being possible to assign them to any of the known causes of the disease, and for which, in fact, no distinct cause can be traced. These are the so-called 'spontaneous' or idiopathic cases of multiple neuritis, which are presumably due to autogenous poisons of some kind.

COMPLICATIONS.—Looking to the varied conditions under which multiple neuritis may arise, it is only natural to expect that the complications should be rather numerous; and this they are found to be. As poisoning by alcohol is the cause of so very large a proportion of the cases of multiple neuritis, we have principally to do with concurrent complications assignable to this cause. Thus the patient may suffer from obstinate symptoms of gastric catarrh, or the liver may be enlarged and hard, or smaller than natural, and other indications of cirrhosis of this organ may exist. It must not be forgotten, moreover, that in the cachectic subjects of chronic malarial poisoning there may be enlargement of spleen as well as of liver. Other complicating effects of alcohol may be due to a chronic or subacute meningitis, the existence of which leads to a great aggravation of the head-symptoms in the form of delirium, or even to a chronic maniacal condition; while in other cases complicating symptoms, due to chronic or subacute spinal meningitis or degenerative conditions of the spinal cord, may be present. Here also—as where gout, or lead, or both combined, have been operative causes of the multiple neuritis—we may find distinct evidences of co-existing renal disease. Pneumonia and phthisis are also frequently present as complications, the latter supervening even in cases where it does not seem to have been present as a cause.

DIAGNOSIS.—It is the great variety in the symptomatology of multiple neuritis, and the fact that it may be associated with actual disease in the spinal cord, which give rise to the principal difficulties in the way of diagnosis. Very many of the cases, however, are so typical in the combination of symptoms presented, as to allow little room for doubt in regard to the proper diagnosis. Thus, more or less paralysis of both feet and both hands, with 'foot-drop' and 'wrist-drop,' or more extensive paralysis of all four limbs of a flaccid type, associated with pains, numbness, and tingling; hyperæsthesia of the skin, marked tenderness of the limb-muscles and perhaps also along the principal nerves, together with absent knee-jerks and the altered electrical reactions which have been described, form such a typical combination that it should be considered to be indicative of multiple neuritis from some cause. And if with this grouping of symptoms there co-exists the combination of cerebral symptoms previously noted, we may feel just as certain that we have to do with a multiple neuritis caused by chronic alcoholic poisoning, even though no distinct evidence of this be at first forthcoming—nay, even though excess in alcohol may be firmly denied by the patient and her friends.

It will be seen that the diagnosis of multiple neuritis from spinal diseases is in the great majority of the cases easy, because pains in the former are mostly prominent symptoms, and because locomotor ataxy is the only form of spinal disease associated with severe pains that could easily be mistaken for multiple neuritis, and that only with

certain exceptional forms of the disease. For there are only four other spinal diseases in which pains in the limbs are apt to constitute prominent symptoms. These are the paralyses associated with cancer of the vertebræ, with scrofulous pachymeningitis, and with cervical hypertrophic pachymeningitis—in each of which (not to mention other characteristic features) there are generally present exaggerated knee-jerks and ankle-clonus—and the somewhat rare affection, syringomyelia, which is almost always characterised by loss of painful and of thermal sensibility in the parts principally affected, while in multiple neuritis these are almost always modes of sensibility that remain unaffected.

There are, however, three varieties of polyneuritis which are especially liable to give trouble in regard to diagnosis. These are, in the first place, acute cases due to chill or to over muscular exercise, in which there happens to be an almost complete absence of pains and other sensory symptoms. Here the condition has to be diagnosed from acute spinal paralysis, or even from acute ascending paralysis. The second set comprises those of the pseudo-tabetic type, in which pains are present, and the diagnosis has to be made from locomotor ataxy. The third class consists of mixed cases, in which multiple neuritis is actually complicated with lesions in the spinal cord or its membranes, or in both. Here there may be at times much room for doubt as to the nature of the affection—that is, whether it is in the main spinal, or in the main peripheral, and to what extent the symptoms of the two conditions can be separated from one another.

Some more definite details must therefore be given in regard to the diagnosis of each of these three forms of the disease.

1. The cases of acute spinal paralysis may agree with some of the more acute cases of polyneuritis in the rapid mode of onset, with or without slight febrile symptoms, in the existence of an atrophic and flaccid form of paralysis in the limbs, together with a more or less complete electrical 'reaction of degeneration' and abolition of knee-jerks. In other forms of polyneuritis, however, the onset is apt to be more gradual and progressive, even in the most acute cases; there is also much more frequently a bilateral symmetry in the parts affected; and even the cases that are most free from sensory symptoms are almost never quite free from such accompaniments, though this is more the rule with cases of acute spinal paralysis. Of course it is only in the early days of these affections that there is room for doubt. After the first few days the progress of the two affections is commonly different. Thus, in acute spinal paralysis the loss of power is at first widespread and simultaneously caused, though after a few days there is a subsidence of the paralysis in some of the parts first attacked. While in multiple neuritis there is a progressive increase in the area of the paralysis during one or more days; and after the paralysis has attained its full development there is no recession of paralytic symptoms till a distinct interval of weeks, or it may be months, has elapsed.

The other disease that may have to be thought of in the early days of one of these acute cases of multiple neuritis is the rare affection known as acute ascending paralysis, concerning which so much doubt exists as to its real nature (*see SPINAL CORD, Special Diseases of: Acute Ascending Paralysis*). This form of disease may be distinguished by the complete absence of sensory symptoms, by

the preservation of the knee-jerks, and by the fact that the paralysis does not progress in the same way that it does in multiple neuritis: in the former it is a more strictly ascending disease, affecting the trunk-muscles after the legs, and then involving the arms; while in the latter the order is almost invariably legs, arms, trunk, and there is also rather less tendency for the bulbar centres to be affected. A little later on, if any doubt should still remain, the absence of muscular atrophy and the preservation of normal electrical reaction would definitely settle the diagnosis in favour of acute ascending paralysis.

2. In reference to the diagnosis of cases of pseudo-tabes from locomotor ataxy, it should be borne in mind that these exceptional forms of multiple neuritis are met with principally after poisoning by alcohol or arsenic, or in the form that is sequential to diphtheria. And then, in reference to the conditions presented, although there may be many characters common to the two affections, there are generally marked differences in the total symptomatology. Thus, in the more rapidly developed pseudo-tabes there are not the characteristic lightning-pains, but more enduring pains, with much more of tenderness in muscles and nerves, together with numbness and tingling in the hands and feet. There is more frequently hyperæsthesia in the limbs, perhaps mixed with patches in which there is analgesia as well as anæsthesia; there may also be some amount of atrophy of muscles, with altered electrical reactions in the direction of the 'reaction of degeneration.' Then, again, there is the absence in multiple neuritis of three signs which are commonly present in locomotor ataxy, viz. the Argyll-Robertson condition of pupil, and temporary bladder-symptoms, together with loss of sexual desire and power. A girdle sensation is also much more likely to be absent in these forms of multiple neuritis, though it has occasionally been met with; and then, again, the lost knee-jerks may return during recovery from multiple neuritis. There still remains the question of the differences in gait characteristic of the two affections. What is known as the *steppage* gait (or the high-stepping gait) has been described as distinctive of multiple neuritis. Its peculiarity is due to the loss of power in the flexors of the ankle, and the consequent dependent attitude of the toes, so that the patient has to lift the foot high, as though he were stepping over a slight obstacle; while in locomotor ataxy, the toes, instead of being dependent, are raised, the heels being generally brought to the ground first, and also in a more irregular and spasmodic manner. Where present the steppage gait is doubtless a sign of value, but it is not always present when it is most wanted in this ataxic class of cases—that is, where paresis of the flexors is, as often happens, present only to a very slight degree.

3. In other cases, where spinal and peripheral lesions co-exist, it may be much more difficult to recognise the real nature of the affection, or, if this can be done, to say which symptoms belong to the one and which to the other set of lesions. In regard to cases where thrombotic softenings, myelitis, or small hæmorrhages co-exist with multiple neuritis (as they may do, more especially, in some few of the cases sequential to the acute specific diseases), it can only be said that such cases are too complicated to be considered here, and that there are

no forms of disease where the aid of an expert is more required in order that a correct diagnosis may be made. It may, however, be added that there are four signs in particular which, when present, may safely be considered to depend in the great majority of cases upon spinal rather than upon peripheral lesions: these are, paralysis of the sphincters, bed-sores, exaggerated knee-jerks with ankle-clonus, and, though less certainly, girdle-sensations.

It should further be borne in mind that there are two affections especially in which the co-existence of peripheral with spinal-cord symptoms is common, viz. acute spinal paralysis and locomotor ataxy. So that where, by reference to the points already laid down, it can be recognised that we have to do with symptoms of double origin, the point to be considered is, whether the central or the peripheral symptoms are primary, and which are merely complicating phenomena. This is a point of considerable importance in regard both to prognosis and to treatment. It is highly important, for instance, to know, in an affection caused by exposure to cold, whether the symptoms are in the main peripheral or whether they are in the main spinal but with some complicating peripheral neuritis. So also it should be remembered that the ataxic cases of multiple neuritis (cases of pseudo-tabes) stand at one end of a series of cases, and at the other stand the somewhat rare cases of locomotor ataxy in which symptoms due to peripheral neuritis are altogether absent; while between these extremes we have almost every kind of transition, furnished either by cases of locomotor ataxy with an increasing number of peripheral lesions, or by cases of pseudo-tabes due to multiple neuritis complicated perhaps by some spinal lesions. The more the patient's symptoms are of peripheral origin, the greater is the relief that is to be expected from treatment.

PROGNOSIS.—Many indications relating to prognosis have already been given, so that little requires now to be added. It may be said, however, that in the great majority of cases life is not imperilled by multiple neuritis. But exceptions to this rule occur in the case of the severer forms of beriberi, and also in the more acute cases occurring in this country, due either to chill, alcohol, or diphtheria, in which the respiratory muscles (including the diaphragm), and the heart, are apt to become paralysed. Otherwise death takes place in multiple neuritis almost solely from the co-existence of one or other of the complications to which reference has previously been made. As to the question of ultimate cure, this, if the cases are not too old and neglected, may in the majority of instances be effected after a prolonged course of treatment. Slight cases may, of course, be cured in the course of a month or two; but in the more severe forms of the disease twelve or eighteen months at least may be required. It is indeed surprising to see the extent to which recovery occurs in this class of cases, even when they are of the worst type, as compared with the amount of improvement that could alone be expected if a similar amount of paralysis with muscular atrophy had been due to spinal rather than to peripheral disease. The signs of commencing improvement to be looked for during the stationary period of the disease are a return of the tingling and numbness in the hands and feet, increased ability to move these parts, together with a gradual improvement in the electrical reactions and

in the firmness and size of the muscles, as well as a progressive diminution of the glossiness of the skin, and sweating in the hands and feet. The return of previously lost knee-jerks may also be looked for.

TREATMENT.—In all cases of multiple neuritis we should, before commencing systematic treatment, have thoroughly decided, as far as it may be possible, what the causal conditions are that have been influential in producing the neuritis, as the first necessity may be to put a stop to some poisoning of the system. It is of the greatest importance to arrive at this knowledge as early as possible, as the longer the poisoning lasts the more protracted and obstinate is the resulting malady. Thus, a rubber-worker should be taken away from his work at once. Steps should be taken to protect the patient from lead or arsenic if either of these have had to do with its development; or, as is most frequently the case, where alcohol is the cause this should at once be cut off completely, whenever the condition of the patient will admit of it. But if too great weakness of the heart be present to permit of this being done, the alcohol should be greatly reduced in quantity at first, and as soon as possible cut off altogether.

In alcoholic cases also, where we have to do with severe pains, mental disturbance, and insomnia, together with gastric symptoms, the greatest care is needed. The latter symptoms may be best checked by keeping the patient upon a strict spoon-diet, pancreatising the milk and beef-tea if necessary, and administering only very small quantities at a time. In the more urgent cases it may be needful at first to have resort to nutrient suppositories. Sleep should be ensured, and the other symptoms relieved as soon as possible by giving morphine, either by subcutaneous injection or by mouth; or, in cases where the symptoms are less urgent, by the administration of full doses of bromide of potassium. At the same time, we must do our best to relieve the local pains and tenderness, by the application of light warm anodyne fomentations, by wrapping the limb in cotton-wool and oil-silk, or occasionally by the use of cold evaporating lotions, if these seem to give more relief to the patient.

In the acute stage of the disease which follows chill, where there are febrile symptoms and perhaps some slight general pains, relief may be derived from salicylate of sodium or salol, given for a few days in full and frequently repeated doses as for rheumatic fever; bromide of potassium may also be given with these drugs night and morning where the restlessness is great and headache is severe. The patient should be kept upon spoon-diet as long as the temperature remains at all elevated; and in all the more severe forms of the disease a water-bed is desirable.

In the less severe cases, to whatsoever cause they may be due, the patients should be kept at rest in bed, partly with a view to warding off any aggravation of the disease, and partly to protect them from cold. In these cases, and also in the more severe forms of the disease, after the acute pains and tenderness have subsided, the diet must be more abundant, though easily digestible and nutritious. Pains may be relieved and sleep favoured by such drugs as acetanilide or phenazone, though where insomnia continues these remedies may be supplemented by bromide of potassium,

chloralamide or trional. At the same time, much may be done by means of tonics to improve the appetite and general health, where, as is so often the case, this has been much impaired by the previous causative conditions. When these have taken the form of malaria, gout, or syphilis, some special treatment may be necessary; otherwise we must trust principally to combinations of iron with small doses of strychnine, aided by extract of malt and cod-liver oil. In cases where there is no marked anæmia, iodide of potassium in six- to eight-grain doses may be given with tincture of nuxvomica instead of the compound of iron, at this stage of the disease, as it may help to allay pains and relieve any accompanying condition of interstitial neuritis. During all this time, in alcoholic cases, alcohol in every form should be entirely forbidden; and to ensure the absolute observance of this order the strictest precautions must be taken. No trust whatever can be placed in the patient in such cases, and injudicious friends (or servants who may be bribed or threatened) should be guarded against. The patient ought to be under the absolute charge of thoroughly reliable nurses, either at home or in some private institution or hospital.

Local treatment must also be assiduously carried on week after week, and month after month, at this stage of the disease. As soon as the tenderness has sufficiently subsided to permit of it, daily massage and gentle passive movements should be had recourse to, and to this very shortly should be added warm or sulphur-baths two or three times a week, and the regular application of galvanism to the atrophied muscles. Even if they do not respond much at first to any currents that can be used without causing pain, the galvanism should be persevered with, and after a time the muscles will begin to respond.

From the first, care should be taken to prevent, as far as possible, the limbs getting into a contracted position. Thus, the knees are apt to be drawn up for the relief of pain in the early stages of the affection, and, if allowed to remain in this position, contractures with rigidity will inevitably result. The 'dropped foot' from weakness of the anterior tibial muscles soon becomes associated with slight contraction of the calf-muscles and shortening of the tendo Achillis. This defective position of the foot may, however, be obviated to a considerable extent if care be taken from an early stage to prevent the foot falling forward by means of some suitable support. This may be most conveniently and effectually done by means of elastic tapes from the anterior part of the foot, fastened on each side of a band encircling the leg just above the knee. Contractions of the wrist and fingers must also be obviated as far as possible. This is best ensured by an early resort to passive movements and massage; and the same means will generally suffice gradually to overcome contractions that may have occurred at the ankles or the knees. Where the former are obstinate, they will in time generally yield when efforts to stand are commenced, and the weight of the body is day by day brought to bear upon the contracted tendo Achillis. It is very rarely indeed that section of tendons becomes necessary.

H. CHARLTON EASTIAN.

NEUROMA (νεῦρον, a nerve).—A tumour connected with a nerve. See NERVES, Diseases of; and TUMOURS.

NEUROSES (νεῦρον, a nerve).—SYNON.: Fr. *Neuroses*; Ger. *Nervenleiden*.

DEFINITION.—Affections of the nervous system occurring without any known material cause, without inflammation or any other constant structural change which can be detected in the nervous centres. In other words, functional affections of the nervous system.

Many of the disorders which may be included here are characterised by symptoms such as neuralgia and convulsions, which also accompany other disorders associated with morbid changes. It is very necessary, therefore, in inquiring into any particular case, not to rest satisfied with the presumption that the disorder is functional until the condition of the nervous centres has been investigated; lest, regarding the symptom as the disease, the central mischief to which it is due may be overlooked. It is highly probable, moreover, that most of what we now regard as functional diseases will, on further investigation, be found to depend upon some corresponding nutritive change in the organ affected—an inference which is being daily verified.

ENUMERATION.—The neuroses may be classified according to the organs or functions involved:—

(a) *Visceral neuroses*, namely, those of the respiratory, circulatory, or digestive organs.

(b) *Localised paralyses*, for instance, palsy of the facial and other peripheral nerves.

(c) *Localised involuntary or reflex movements*, such as spasm of the facial nerve and writer's cramp.

(d) *Disorders of general sensibility*, including the various forms of neuralgia—trigeminal, cervico-occipital, sciatic, crural, &c.

(e) *General neuroses*, namely, chorea, epilepsy, catalepsy, hysteria, and allied affections.

(f) *Disorders of the mental faculties*—hypochondriasis, melancholia, and other forms of mental derangement.

For detailed descriptions of these, see the articles on the various organs concerned.

P. W. LATHAM.

NEUSCHMÉCKS.—See SCHMÉCKS.

NICE, on the French Riviera.—Warm, dry, bracing, winter climate. Temperature 50° F. See CLIMATE, Treatment of Disease by.

NICTITATION (*nictito*, I wink often).—A rapid involuntary winking of the eyelids, usually due to some nervous disturbance. See CHOREA; and FACIAL SPASM.

NIEDERBRONN, in Lower Alsace.—Muried saline waters. See MINERAL WATERS.

NIEDERSELTERS (Selters), in Nassau.—The well-known muried alkaline table-waters. See MINERAL WATERS.

NIGHT-BLINDNESS.—See NYCTALOPIA.

NIGHTMARE.—This is a condition characterised by an abiding sense of discomfort or extreme uneasiness, occurring in the midst of a disturbed sleep, sometimes associated with a feeling of weight at the epigastrium, in conjunction with more or less definitely oppressive dreams. It is principally associated with the taking of a heavy meal or of indigestible food before going to sleep by some persons, especially those of a nervous temperament, whose digestion is weak. A closely allied condition is,

NIPPLE, DISEASES OF

however, apt to be met with as a consequence of brain-exhaustion and chronic disturbance of sleep in those who are overworked, by application either to study, business details, or literary pursuits. Such a condition also has its affinities with certain forms of incipient delirium, occurring either in various febrile diseases or as a result of alcoholic excesses. See SLEEP, Disorders of.

H. CHARLTON BASTIAN.

NIGHT-SIGHT.—See HEMERALOPIA.

NIGHT-TERRORS OF CHILDREN.—The child who is the subject of this ailment may have gone to bed apparently in perfect health and gone to sleep, but will suddenly arouse the household some two hours later with a piercing shriek, and will be found in an agony of terror pointing at some imaginary object and imploring that it be taken away, or crouching in a corner of the bed in the hope of getting away from the dreaded thing. As a rule with judicious soothing the child will before long drop off to sleep again and may sleep perfectly soundly for the rest of the night, and in the morning have no knowledge of the occurrences of the previous evening; the same scene may be enacted on subsequent, but not necessarily successive, nights. If the child suffers from any form of gastro-intestinal disturbance or from 'adenoids,' it is probable that the trouble would be of the nature of nightmare and would be removed by appropriate treatment; but on the other hand there may be no such exciting cause discoverable, while the child is of a highly nervous disposition and there is a family predisposition to neurosis. According to Coult's the true subjects of this ailment all belong to this class, and in them it is not infrequently the forerunner of epilepsy, and has been preceded at an earlier period of life by the occurrence of infantile convulsions. It is equally common in the two sexes, and is most often met with about the commencement of the second dentition, but may occur in children as young as two years. Small doses of bromide of ammonium at bedtime (a grain for each year of the child's age) is the best treatment, though antipyrine has been credited with the power to prevent an attack if given at bedtime. Such children should not be left alone at night or in the dark. If the attack occurred at the time of the second or first dentition, a dental surgeon should be consulted, and in all cases attention should be paid to the diet.

JOHN ABERCROMBIE.

NILE, The.—A very dry winter climate. Mean temperature, winter, 57° F. Unsuitable for cases of active pulmonary disease. See CLIMATE, Treatment of Disease by.

NIPPLE, Diseases of.—SYNON.: Fr. *Maladies du Mamelon*; Ger. *Krankheiten der Brustwarze*.—Some of the more ordinary affections of the nipple will be found described under BREAST, Diseases of; and LACTATION, Disorders of. Here it is proposed to treat of certain graver diseases, which claim a separate consideration.

1. Cancer.—The nipple may be the seat of epithelioma, which commonly commences as a crack or fissure, with an indurated base, often in the areola or at its junction with the nipple. It may be a squamous-celled carcinoma, in which case it differs in no respect from similar disease of the integument of adjoining parts. In some cases it is

a duct-cancer, the more superficial part consisting of columnar cells, and the deeper part of spheroidal epithelium. Hard carcinoma too may attack the nipple, involving its deeper structures, and producing general induration and enlargement, so that the diseased mass projects from the summit of the breast like a knob or large nut. The disease probably originates in the epithelium of the galactophorous ducts, or in that of the sebaceous glands.

2. **Paget's Disease.**—Of greater interest than either of the preceding is an affection frequently associated with malignant disease of the breast, to which Paget first drew attention—an *eczematous* condition of the nipple and areola. It may occur in the form of a dry, scaly, or branny eruption, affecting the entire surface of the areola and nipple, which is darker coloured, a little firmer, and less pliant and elastic than its fellow. Or, with more characteristic signs of inflammation, small vesicles or pustules may form, and, breaking or being rubbed off, may leave behind them tiny scabs or ulcers, or a surface raw and red. Either condition may exist for many months or even years with little alteration, and with scarcely any tendency to spread beyond the margin of the areola. But the second form, causing more irritation than the first, is often subjected to treatment; and being very difficult to cure, is sometimes so severely treated with caustics that destruction ensues, not of the disease, but of the nipple, which appears to have been gradually eaten away by the eczematous affection. Both forms are uncommon, but they are rare before the middle age. A study of their clinical and pathological characters leads to the conclusion that they are due to inflammation. The disease has been noticed in men as well as women.

TREATMENT.—This disease may be treated by protecting the parts with a carefully adjusted, ventilated shield, and by the application of vaseline, or liniment of lead and oil, or similar soothing dressing. But it is very intractable, in some cases apparently incurable. It might seem as if an affection so trivial were not worthy of so much attention; but unfortunately there appears the strongest reason to believe that these conditions of the nipple and areola are not infrequently the precursors of carcinoma of the breast, sometimes by only a few months, more often by a period of years. It is probable, too, that the carcinoma is directly due to the eczematous disease; for it induces changes in the epithelium of the ducts which can be traced deeply into the substance of the breast, whose acini become at length distended with proliferating epithelium. On this account it has been proposed, when all the lesser methods of treatment have been used in vain, to remove the entire breast. Opinions, which are divided on the necessity of this severe measure, are united in its favour when, with the superficial inflammation, there exists an appreciable induration, however slight, within the breast. Care must be taken not to confound these eczematous affections of the nipple and areola with those more widely diffused superficial inflammations of the breast, with which they have little in common, either in the obstinacy with which they resist treatment, or in the deeper disease to which they may give rise.

3. **Sarcoma.**—Sarcoma occasionally occurs in the skin covering the breast. It is either spindle-celled or melanotic: in either case its early removal is advisable.

4. **Benign Formations.**—Among the innocent tumours of the nipple and areola of the breast are (1) *lupus*, which should not be mistaken for the malignant dermatitis known as Paget's disease of the nipple; (2) *molluscum contagiosum*, small pearly white tubercles which may infect the cheeks and eyelids of any child suckled at the breast; (3) painful *subcutaneous fibromata*, which cause intense neuralgia of the breast and local tenderness; (4) *sebaceous cysts*, formed in some of the 15–20 sebaceous glands situated in the areola; (5) *nevi*; and (6) the *pedunculated fibromata* of the nipple. The fibromata often contain glandular elements, they may be warty in appearance, and are so well supplied with blood by arteries which run in the pedicle, that they must not be snipped off without previous ligature.

5. **Syphilis.**—Syphilis affects the nipple and areola of the breast in the primary, secondary and tertiary stages of the disease. Direct infection is usually the result of suckling a syphilitic child while it has mucous patches about its mouth. *Primary* sores, therefore, are met with among wet nurses and in those persons who consider it an act of courtesy to give an occasional feed to a neighbour's child. One or both breasts may be affected by a shallow, circular and painful ulcer with a smooth, glazed surface, and only very slight parchment-like induration at its base. Sometimes there is only a slightly indurated fissure, or the induration may be diffuse without ulceration; occasionally the ulceration is phagedænic. The true nature of the affection is apt to be overlooked since there is no reliable history, and the sores are multiple and very often atypical. In such cases the very slight amount of pain attending the fissure or ulcer and the early enlargement of the axillary glands, which are hard and bullet-like, should raise a suspicion of primary syphilis; while the appearance of secondary symptoms with an examination of the suspected child, where possible, will confirm the diagnosis. The eruptions of *secondary* syphilis and condylomata may occur upon the areola, while the circular and irregular ulcers of *tertiary* syphilis may occur upon the nipple as they do in other parts of the skin. The *treatment* of each of the conditions mentioned above does not differ either locally or constitutionally from that adopted for syphilis.

6. **Tuberculosis.**—Tuberculosis but rarely affects the nipple or its areola in either sex. It needs prompt surgical treatment owing to the tendency shown by the inflammation to spread along the ducts and lymphatics until the breast becomes affected.

HENRY T. BUTLIN.
D'ARCY POWER.

NOCTAMBULATION (*nocte*, in the night; and *ambulo*, I walk).—A term for sleep-walking. See SLEEP, Disorders of.

NOCTURNAL INCONTINENCE.—Involuntary escape of urine during sleep. See MICTURITION, Disorders of.

NODE (*nodus*, a swelling).—A circumscribed swelling on the surface of a bone, connected with the periosteum, and usually due to syphilis. See BONE, Diseases of; and SYPHILIS.

NOMA (*νομή*, a corroding sore; from *νέω*, I devour).—**SYNON.**: Fr. *Nome*; Ger. *Wasserkrebs*. A synonym for cancrum oris. See CANCRUM ORIS.

NOSE, Clinical Examination of.— Before proceeding to examine the nasal passages a preliminary inspection of the external parts should be made. The patency of the passages should be tested by successively closing each passage, and directing the patient to breathe through the other. The nasal passages can be inspected from the front through the anterior nares, or from the back, through the naso-pharynx. The former method is termed 'anterior rhinoscopy,' the latter 'posterior rhinoscopy.' Exploration with the probe, and digital palpation, are often necessary supplements to inspection.

In order to examine the nasal passages from the front, the observer should be seated upright facing the patient. It is always better to employ reflected light, in the same manner as for examination of the larynx (*see* LARYNX, EXAMINATION OF). Having concentrated a bright circle of light on the patient's nose, we can obtain a view of the interior of the vestibule by making the patient tilt the head slightly back, and raising the tip of the nose with the thumb. In order to examine the interior of the nasal fossa, a speculum must be used to dilate the cartilaginous aperture. There are several different forms of nasal speculum, but Duplay's bivalve speculum is perhaps the most generally useful. The speculum should be inserted gently with the thumb and forefinger of the left hand, and the blades separated slowly, the patient's head being tilted slightly backwards while this is being done. The anterior end of the inferior turbinated body will first attract attention, forming a rounded prominence projecting from the outer wall. If the patient's head be now tilted a little forwards, the convex surface and lower border of the inferior turbinated body can be traced backwards for a considerable distance, or even for the whole length, presenting usually an irregular wavy outline. The floor of the nasal passage can often be traced to the posterior extremity; and, if a strong light be directed back along the floor, the posterior wall of the pharynx can sometimes be discerned. If the patient's head be thrown backwards, the middle turbinated body will be seen above and behind the inferior. The anterior border, and the angle between this and the inferior, are the parts chiefly seen. Between the middle turbinated body and the septum is a narrow space, known as the olfactory slit, which can only be imperfectly illuminated. The spaces beneath the inferior and middle turbinated bodies, respectively, can be illuminated to a limited, but variable extent. When the patient's head is thrown well back, the fore part of the roof will be brought into view, but the superior turbinated body cannot be seen.

The actual extent of the parts seen by anterior rhinoscopy varies much in different cases. A deflected septum is a serious obstacle. Vascular turbulence of the inferior turbinated body, especially at the anterior end, often interferes with the view. This swelling can be reduced by the application of a 5-per-cent. solution of the hydrochlorate of cocaine. By its constricting effect on the blood-vessels, cocaine contracts the mucous membrane of the nose to a greater or less extent, wherever it is applied, and is an invaluable aid to a thorough rhinoscopic examination of the nasal passages.

By the method of examination known as posterior rhinoscopy, the posterior nares and naso-pharynx can be inspected. A small mirror, about half or five-eighths of an inch in diameter, is used in the

examination. A small laryngeal mirror serves the purpose, but the mirror should be attached to the stem at more nearly a right angle than is usual for laryngoscopy, and it is convenient to have the handle slightly bent to follow the curve of the tongue. A rhinoscope such as Michel's, however, is much more convenient. In this instrument the mirror is in the same plane as the handle, and can be raised to any angle by pressure on a spring.

The patient sits upright, with the head inclined slightly forwards, and is directed to open the mouth and breathe quietly and naturally. The light is concentrated from a reflector on the palate and pharynx, in the same manner as in laryngoscopy. The tongue must generally be depressed with a spatula. One with the handle at right angles to the blade is most convenient. The rhinoscopic mirror, previously warmed, is introduced rapidly, with its reflecting surface upwards, to one or other side of the uvula, close to, but not touching, the wall of the pharynx. By depressing the handle or by pressing on the spring, according to the form of rhinoscope used, the mirror can be made more vertical, and by various movements of the mirror an image of the different parts can be obtained. Difficulties may occur in the examination. The commonest is the drawing up of the uvula and soft palate against the pharyngeal wall as soon as the examination is begun. The patient should be directed to breathe quietly through the nose, and the effort to do this will cause the velum to hang away from the pharyngeal wall. If this does not succeed, the patient should be made to emit the French nasal sound *en*, or *on*. This will often succeed in giving a view of the parts. Painting the fauces with a 10-per-cent. solution of the hydrochloride of cocaine will often be an assistance. In certain cases, where the depth of the pharynx is small and the soft palate long, a view can only be obtained by drawing the soft palate and uvula forwards by means of some form of palate-hook.

Only a limited portion of the post-nasal region is seen reflected in any one position of the mirror. When the mirror is first raised into a nearly vertical position, the posterior surface of the velum is brought into view. By inclining the mirror to a more horizontal position, the septum appears as a sharp, whitish ridge, which serves as a landmark to the parts in this region. On either side of the septum, the ovoid openings of the nasal fosse, the choanæ, may be brought into view by slightly turning the mirror. Each choana is largely occupied by the posterior ends of the turbinated bodies, the most conspicuous of which is the middle. The inferior is largely hidden by the soft palate, as is also the lower end of the septum. By inclining the mirror to one side, the depression leading to the Eustachian orifice is seen, bounded above and behind by a prominent ridge. By bringing the mirror to a nearly horizontal position, the vault of the naso-pharynx and the region of the pharyngeal tonsil are brought into view.

The probe is often necessary to supplement anterior rhinoscopic examination. By its means the consistence, mobility, and mode of attachment of swellings, hypertrophies, and new-growths can be determined, and the presence of sequestra, foreign bodies and rhinoliths made out. Occasionally a probe, suitably bent, is useful to determine the condition of the parts seen in the posterior rhinoscopic image.

Digital palpation through the anterior nares is rarely practised, but in the naso-pharynx it is an extremely important method of examination, and when, as in children, posterior rhinoscopy is difficult or impossible, digital exploration is the only method open to us. For the purpose of this examination the patient is seated, and the operator stands facing the patient's right side. The left arm is passed round the patient's head, and the left hand rests on the patient's chin. The head is thus steadied. The right forefinger is passed rapidly to the back of the pharynx, inserted behind the soft palate, and then pushed boldly upwards. In this way the posterior ends of the turbinals, the pharyngeal tonsil and other structures can be rapidly explored. A prop may be placed between the teeth, as a preliminary, but it is not really necessary.

JAMES BARRY BALL.

NOSE AND NASO-PHARYNX, Diseases of.

SYNON.: Fr. *Maladies du Nez et du Pharynx Nasal*; Ger. *Krankheiten der Nase und des Nasenrachenraums*.

The diseases of the nasal orifices, nasal fossae, septum nasi, naso-pharynx, and of the accessory cavities of the nose will be considered under the following headings:—

1. Acute Rhinitis and Naso-pharyngitis.
2. Chronic Nasal and Naso-pharyngeal Catarrh:
(a) Simple Chronic Rhinitis; (b) Hypertrophic Rhinitis.
3. Chronic Atrophic Rhinitis (including Ozena).
4. Rhinorrhoea.
5. Post-Nasal Vegetations (Adenoid Growths).
6. Syphilis of the Nose.
7. Tuberculosis of the Nose (Lupus and Tuberculo Disease).
8. Affections of the Nasal Septum.
9. Foreign Bodies in the Nose (including Rhinoliths).
10. Parasites in the Nose.
11. Rhinoscleroma.
12. Nasal Diphtheria.
13. Tumours of the Nose and Naso-pharynx.
14. Affections of the Accessory Sinuses (Maxillary, Frontal, Sphenoidal, and Ethmoidal).
15. Reflex Nasal Neuroses.

EPISTAXIS, HAY-FEVER, and OLFACTORY SENSE are dealt with in separate articles.

1. Acute Catarrhal Rhinitis and Naso-pharyngitis.—SYNON.: Acute Nasal and Naso-pharyngeal Catarrh; Acute Coryza; 'Cold in the head.'

ÆTIOLOGY.—Acute coryza is usually an independent affection, but it may be found in association with some other malady, such as one of the specific eruptive fevers. The disease is most frequent in cold and changeable weather, and is almost certainly of microbic origin. It has an abrupt onset and usually runs a regular course. Sometimes it is found in an epidemic form, especially when many individuals live under the same roof and share the same rooms. Acute rhinitis may also be caused by irritating fumes and certain drugs, especially iodide of potassium; and it is occasionally a prominent feature in influenza. In most cases chill is the accreted cause. See CHILL.

SYMPTOMS.—The patient feels out of sorts, has a sense of chilliness, slight headache, and a feeling at first of irritation and then of dryness and fulness in the nose, with frequent attacks of sneezing.

There is occasionally a rise of temperature (99.5° to 101°) during the first two days of the attack; and the patient complains of feeling tired and heavy in the head. His pulse is quickened; the skin feels hot and dry; and pains in the back and limbs are frequently complained of. Engorgement of the submucous erectile tissue and rapid œdematous swelling of the mucous membrane lead to blocking of the nasal passages. The changes are most marked in the mucosa and submucosa covering the inferior turbinal bones. This sudden obstruction to nasal respiration necessitates breathing through the mouth, which intensifies the dryness of the pharynx and naso-pharynx. At first, notwithstanding the tumefaction and hyperæmia, there is no secretion from the nasal mucosa. Soon, however, a thin serous acid discharge which frequently excoriates the margins of the nostril and the upper lip is poured out, and this, in the course of two days or less, generally becomes muco-purulent. The sense of smell is largely impaired or lost. The catarrhal process may spread up the nasal duct and lacrymal passages and involve the conjunctiva, or may extend into one of the accessory cavities of the nose, most commonly the frontal sinus. Very frequently the naso-pharynx is secondarily involved; in many cases, however, particularly in children in whom post-nasal growths are present, the catarrhal process commences in the naso-pharynx and spreads thence downwards to the nose.

When the *naso-pharynx* is involved the symptoms are those of dryness and heat, described by the patient as being 'behind and above the nose.' Soon a thick viscid muco-purulent secretion is observed, which the patient has to 'hawk' away, as blowing the nose does not seem to clear the naso-pharynx sufficiently. The process is very prone to involve the Eustachian tube and to give rise to deafness, tinnitus aurium, and pain in the ear—these symptoms being caused by obstruction to the lumen of the Eustachian tube and retention of mucous, muco-purulent, or even purulent secretion in the tympanum. Every succeeding attack of acute naso-pharyngeal catarrh is prone to cause further enlargement of any existing post-nasal growths and to run into a chronic form of naso-pharyngeal catarrh which is a serious menace to the ears.

An uncomplicated cold in the head lasts only a few days, generally from four to seven. It must be remembered that an acute rhinitis may be the first symptom of an acute specific fever, particularly of measles or of influenza.

TREATMENT.—Mild cases call for little treatment beyond avoidance of exposure. In others the attack can be cut short by frequently repeated doses (4 grs.) of quinine. If the rise in temperature be above 100°, or if there be any complication, rest in bed is called for. The employment of diaphoretics gives relief to most of the symptoms. A mixture consisting of Liquor. Ammon. Acetat. ʒj, Spirit. Ether. Nitrosi mxx, and Aquæ Camph. ad ʒss, may be given four times daily. At bedtime the feet should be kept for several minutes in a foot-bath containing water as hot as can be borne, and when the patient is in bed a hot drink and ten or twelve grains of Dover's Powder should be given. The irritation and obstructive swelling can be temporarily relieved by spraying with a 1-per-cent. solution of hydrochloride of cocaine; this, however, must be used with caution. The relief (lasting half to three-quarters of an hour) obtained by the

cocaine-spray is most grateful to the patient, and frequently in the case of a busy man very valuable. In infants the obstructive swelling may cause urgent dyspnoea, laryngeal spasm, and inability to suck. These symptoms can generally be temporarily relieved by spraying the nostrils with a few drops of the cocaine-solution.

Acute Purulent Rhinitis presents the symptoms of acute catarrhal rhinitis, but the discharge is purulent and sometimes foetid. When met with in the infant a few days after birth it is probably of gonorrhoeal origin. In older children and adults it is found as a sequel to diphtheria, measles, or scarlet fever, and in general yields readily to a spray containing five grains each of sodium bicarbonate, borax, and common salt to the ounce of water. For extensions of the acute catarrhal process to the frontal and other sinuses, see Affections of the Accessory Cavities of the Nose.

2. Chronic Nasal and Naso-pharyngeal Catarrh.—Under this heading may be described (a) Simple Chronic Rhinitis and Naso-pharyngitis; (b) Chronic Hypertrophic Rhinitis and Naso-pharyngitis; and (c) Chronic Atrophic Rhinitis and Naso-pharyngitis.

The first two conditions cannot be rigidly differentiated, the second type being commonly, if not always, a more advanced stage of the first. They will therefore be in part described together.

(a) *Simple Chronic Rhinitis*.—**SYNON.** : Chronic Catarrhal Rhinitis; Chronic Coryza.—In this condition there is an increased irritability of the nasal mucosa, especially of that covering the middle and inferior turbinated bones. The sufferer catches cold very frequently, and complains of a stuffy feeling in the nose with obstruction, generally temporary and partial, of one or both nasal passages. This condition is in children commonly found in association with post-nasal adenoid vegetations. There is an increase in the amount of the secretion from the mucous membrane, which is at first watery but becomes, as the condition progresses, thick and viscid. The stuffiness in the nose is always worse at night, and the patient wakes in the morning with a dry mouth and pharynx due to mouth-breathing. If in this stage the nose be examined the mucosa is found but slightly altered. There is frequently, however, a mild degree of swelling and congestion, with, in some cases, commencing hypertrophy. There appears to be a loss of tone, of the arterioles, with consequent distension of the erectile tissue covering the two lower turbinated bones. The sense of smell is but little affected. Extension of this chronic catarrhal inflammation frequently involves the naso-pharynx, causing chronic post-nasal catarrh. In this condition the tenacious viscid mucus which is met with in the naso-pharynx is with difficulty removed by hawking. During the day this usually gives little trouble, but when the patient awakes dry-mouthed in the morning he is much worried by the continual efforts required to dislodge the mucus from the naso-pharynx. In America and South Africa, owing chiefly to the inhalation of dust, post-nasal catarrh assumes a far more severe type than in this country, and a much larger proportion of the population are affected.

TREATMENT.—See (b) Chronic Hypertrophic Rhinitis.

(b) *Chronic Hypertrophic Rhinitis*.—**SYNON.** : Chronic Hypertrophic Nasal Catarrh.—This condition is commonly a sequel of simple chronic catarrh,

and is frequently found in association with post-nasal vegetations. The mucosa of the nose and naso-pharynx is thickened, and the enlargement is chiefly found on the two lower turbinated bones, on the lower part of the septum nasi, and around the orifices of the Eustachian tubes. In addition to post-nasal vegetations other causes of chronic hypertrophic rhinitis are abnormalities in the nasal passages which cause obstruction to free nasal respiration or hinder the removal of the secretion, such as spurs or deviations of the septum, polypi and foreign bodies. In many cases, however, no real cause can be assigned. Though the condition may be met with at any period of life, by far the largest number of cases commence in childhood.

ANATOMICAL CHARACTERS.—There is generally redness of the nasal mucosa, which presents thickenings irregularly distributed, generally most marked at one or other end of an inferior turbinated bone or along its whole length. That this condition is a real overgrowth of the mucosa may be shown by the application of a solution of cocaine (5 per cent.) to the affected part. This only slightly reduces the swelling, whereas in cases of dilatation of the erectile tissue, as in simple chronic rhinitis, the application of cocaine causes a very remarkable shrinkage. The hypertrophy frequently affects the anterior segment of the inferior turbinal, and may give rise to a somewhat pedunculated growth of a reddish or purplish colour. This condition is most liable to obstruct nasal respiration when associated with a spur growing from the same side of the septum nasi. Hypertrophy of the posterior ends of the inferior turbinals is recognised by posterior rhinoscopy, or by digital examination. It may be seen as a smooth or, more frequently, as a lobulated ‘mulberry-like’ growth of greyish red or purplish hue projecting into the naso-pharynx, and sometimes all but completely obstructing it. This condition is to be sought for in all cases of impediment to nasal respiration where no post-nasal vegetations, enlarged tonsils or anterior nasal obstruction can be found. Hypertrophy of the middle turbinal is less frequent, and, where present, less marked, but it may touch the septum, and impede respiration through the middle meatus of the nose.

SYMPTOMS.—Obstruction to nasal respiration is constantly present, but is found in varying degrees. It is frequently scarcely noticeable during the daytime, but is troublesome at night when the throat and mouth become dry; and sleep may thus be disturbed. When the Eustachian tubes are involved, deafness, tinnitus, and otitis media may ensue from the resulting obstruction. The voice may become thick or nasal. Sneezing is frequent and sometimes violent, and in certain patients asthmatic seizures and other reflex symptoms—the so-called nasal neuroses—are observed.

TREATMENT.—Treatment will vary according to whether or no there is hypertrophy of the nasal mucous membrane. In strumous children cod-liver oil and tonics are indicated, but in the vast majority of cases the treatment is purely local. (1) When post-nasal vegetations, distinct nasal spurs, or any real impediment to nasal respiration exists, removal of the obstructive body is generally called for. (2) The thorough cleansing of the nasal passages is most essential, and must never be omitted. The nasal douche should never be used, owing to the liability of fluids to enter the tympanic cavity through the Eustachian tube and thus occasion

acute otitis media. A nasal spray should be employed, and the nasal passages should be sprayed twice or thrice daily with an alkaline mildly antiseptic solution, which should be warmed prior to use. An excellent spray-solution is the following: R. Sodii Bicarbonatis, gr. x; Boracis, gr. viij; 'Listerine,' ʒj; Aquæ, ʒj. This softens and washes away the mucus, and thus satisfactorily cleanses and purifies the mucous membrane. (3) In cases of marked hypertrophy of the mucosa operative interference must be undertaken. Where the hypertrophy assumes a polypoid or strawberry-like form it is best removed by a snare, either the cold snare, using piano-wire, or the electric cautery, employing a platinum-wire loop. In cases in which the hyperplasia is more general, the best results are obtained by the employment of the electric cautery. Two or three linear cauterisations may be made from behind forwards over the hypertrophied mucosa, parallel with the lower turbinal margin. Care must be taken not to cauterise the septum lest adhesion between the two raw surfaces occur, when the sloughs have been cast off. A bead of chromic acid is often effectual in destroying the hypertrophied mucosa, but is very inferior in every respect to the electric cautery. A solution of cocaine (5 to 10 per cent.) brushed on the mucous membrane renders cauterisation practically painless. A general anæsthetic is not required, and is inadvisable. After cauterisation the patient need not, as a rule, be confined to bed or even to the house. No after-treatment is required beyond the use of the above-mentioned nasal spray. Very rarely is it necessary or advisable to remove any part of the turbinated bones themselves. Should occasion demand it, the inferior turbinated bone may be removed under nitrous-oxide gas, by means of Carnalt Jones's turbinotome; or portions of the bone may be cut away with one of the forms of punch-forceps. In such cases the bleeding is always free, and sometimes very abundant. It is readily arrested by plugging with double-cyanide or iodoform gauze, which can generally be removed after a few minutes without causing any recurrence of the bleeding. If the electric cautery be thoroughly and skilfully used few cases will call for the removal of any portion of the turbinated bones.

3. Chronic Atrophic Rhinitis.—SYNON.: Chronic Fœtid Rhinitis; Ozæna (ὄζη, a stench); Fr. *Ozène*; Ger. *Stinknase*.

The term 'ozæna' has been applied to diverse ulcerative nasal conditions, in which fœtor is a prominent symptom; thus syphilitic ozæna, cancerous ozæna, &c., are sometimes described. The term 'chronic fœtid rhinitis' would perhaps best differentiate the condition described below. A dry atrophic condition of the nasal mucous membrane is sometimes seen without any accompanying fœtor.

PATHOLOGY.—The essential conditions encountered are atrophy of the nasal mucosa and of the subjacent bones, more particularly the turbinated bones, and a peculiar sickening fœtid odour. The cause of the atrophy of the mucous membrane, erectile tissue and underlying bones is unknown. The nasal secretion when it is first formed is entirely inodorous, and only acquires its disgusting stench some hours afterwards. The odour is due to the action of a specific micro-organism, the *Bacillus fœtidus ozænae* (Hajek), a cultivation of which outside the body reproduces the fœtor characteristic of ozæna. Ozæna commences as a rule in childhood

or youth, the large majority of cases giving a history of the trouble beginning between the tenth and twentieth years of life.

In cases in which atrophic rhinitis is found free from any fœtor it will generally be discovered on inquiry that the symptoms commenced much later in life (e.g. at, or after, the age of forty). Though delicate children seem to be more prone to become the victims of fœtid atrophic rhinitis, it is very frequently encountered in persons who are otherwise in perfect health. It is five times more frequent in the female sex than in the male. It is probably not contagious, and when, as is not infrequently the case, it occurs in two or three members of the same family, hereditary predisposition to the atrophic process may be assigned as the cause.

SYMPTOMS.—On examining the patient the characteristic fœtid odour is at once perceived. It is noteworthy, however, that the patient, though his sense of smell is usually not entirely lost, is quite unconscious of it. The nasal chambers, when examined by the aid of the speculum and rhinoscopic mirror, present a very roomy appearance; the mucosa and subjacent bones, particularly the inferior turbinated, are atrophied to a marked degree. Owing to the shrinkage of the mucous membrane, which has a dry and thin appearance, it is possible to see much farther into the nose than is normally the case, and frequently the openings of some of the accessory sinuses (e.g. the frontal) and even of the Eustachian tubes can be seen. The mucous membrane is in large part covered by crusts, which are very adherent, and result from the drying of the muco-purulent secretion of the mucosa. On removing a crust the subjacent mucous membrane may show light excoriations, but there is no ulceration. The nasopharynx has a similar dry appearance, and may contain crusts and muco-pus; and the atrophic process may affect the mucosa of the pharynx, and even, in rare cases, of the larynx.

DIAGNOSIS.—The diagnosis presents no difficulty: the association of the roominess of the nasal passages, the atrophy of mucous membrane and turbinated bones, the crusts and muco-pus, and the characteristic stench exhaled taken together are unmistakable.

TREATMENT.—Ozæna is still an incurable disease, though simple treatment robs it of its worst symptom. This consists in thoroughly cleansing the nose of the crusts and muco-pus. For this purpose the nasal spray should be employed at least twice daily (night and morning). Strong antiseptics applied to the nasal mucosa are inadvisable, and the best results will generally be obtained by the employment of a mild alkaline solution such as the following: R. Sodii bicarb. gr. viij, Boracis gr. viij, Sodii Chloridi gr. iv, Glycerini m. xxx, Aquæ ad ʒj. The important points are to use the spray-solution warm and liberally, so as to soften and remove the crusts. The vast majority of cases of ozæna require no other treatment. In very neglected cases it may be necessary to remove the crusts with a probe. Some patients derive benefit from the use of paroline used in an atomiser. Gottstein's method of treatment consists in preventing the formation of crusts by stimulating the mucous membrane to pour out an increased amount of watery secretion. With this object in view a plug of cotton-wool is introduced into the nostrils alternately and retained for some hours. The plugs may be soaked in glycerine prior to their introduction. The general condition

will in many cases require attention; thus tonics, good food, and cod-liver oil are useful adjuvants in cases in which anæmia or a scrofulous tendency is met with.

4. **Rhinorrhœa.**—By this name is described a somewhat rare condition, the chief symptom of which is a profuse discharge—generally pale, serous, and watery, but sometimes milky or of the colour of urine—of nervous origin and recurring with a certain regularity. The discharge may be bilateral or may come from one nostril only, and commonly occurs about once a day, lasting from a few minutes to some hours, and ceasing quite suddenly. It may be preceded by some symptoms of irritation in the nose and sneezing, but frequently none such are observed. The fluid comes from the nasal mucosa, which is commonly, in these cases, oedematous and hypertrophied. The treatment consists in cauterising the mucosa covering the middle and inferior turbinated bones, and in giving an astringent nasal spray, e.g. Alum (gr. iv) or Iron-alum (gr. ij) dissolved in an ounce of distilled water. This treatment, as a rule, only mitigates and does not cure this distressing condition, but frequently after months or even years the discharge ceases as suddenly as it commenced, and does not return.

Patients are sometimes seen who have sustained a fracture of the base of the skull in the region of the ethmoid bone, and who suffer, especially in certain positions of the head, from an escape of cerebro-spinal fluid. This condition must not be mistaken for that described above.

5. **Post-nasal Vegetations.**—**SYNON.** : Adenoid Vegetations.—Post-nasal Growths consist of an hypertrophy of 'Luschka's tonsil,' which is a mass of lymphoid tissue situated on the vault and on the posterior wall of the naso-pharynx, and is constantly present in young subjects. The pharyngeal tonsil, when examined in a young child, is found to be bounded on each side by the orifice of the Eustachian tube, and to present on its surface several vertical furrows, which partially subdivide it. This lymphoid structure, which is soft and bulky in the young child, tends to become partly absorbed and in part to undergo a fibrous transformation as adult life is approaching; hence adenoid growths in adults are always firmer and more fibrous than in the young child.

ÆTIOLOGY.—The condition may be observed in infants a few months old, but commonly comes under notice between the third and eighteenth years of life. Heredity certainly plays an important part in its causation, and frequently several members of a family are affected. The growths are frequently found along with hypertrophied tonsils, enlarged cervical glands, and thickening of the nasal mucous membrane, but are not uncommonly observed free from any such association.

SYMPTOMS.—Frequently there are no striking symptoms; and in general the patient is brought for treatment on account of some complication which has arisen, especially ear-ache or otorrhœa.

In infants with bulky adenoid vegetations sucking the nipple may be difficult or impossible. Mouth-breathing is the rule, especially during sleep; and snoring, with semi-suffocative attacks, is frequent. The open mouth, obliteration of the nasolabial fold, short upper lip, and drawing downwards of the inner canthi of the eyes give a vacant, semi-idiotic appearance to the face, which is very characteristic. The voice is modified, and there is

inability to pronounce properly *m*, *n*, *ng*, *th*, *z*, and *t*; *m* is generally, and *n* frequently, mispronounced *b*.

DIAGNOSIS.—There are two methods in general use: (1) Posterior rhinoscopy, which can be employed in less than half of all cases, as it is useless in children under 8 or 10 years of age, and in those who are unmanageable and fractious; and (2) Digital exploration, which gives entirely satisfactory information. The index-finger is passed rapidly into the mouth along the under surface of the soft palate and up into the naso-pharynx. This method of examination is instantaneous, not really painful, and by means of it the presence, size, consistence, and relations of the adenoid mass may be determined. The examining finger must be aseptic, and the examination conducted with the utmost gentleness. On the posterior pharyngeal wall are frequently to be observed in children soft oedematous gelatinous-looking granulations, which increase in size and number as they approach the naso-pharynx. These, when seen, always indicate the presence of post-nasal growths. They are hypertrophied patches of the lymphoid tissue of the part, histologically indistinguishable from 'adenoids' except that they lack their ciliated epithelial covering.

Post-nasal growths present themselves in two very distinct types: (1) In one the growths are soft and oedematous, easily lacerable, highly vascular, and prone to bleed. They hang down as spongy papillary masses, and give to the examining finger a sensation which has been aptly compared to that of touching a bunch of earthworms. (2) Much more frequently the mass presents the character of a distinct tumour. It is firm, fibrous, and smooth, except where it is vertically furrowed, and gives the impression of a tense elastic tumour, springing from the vault and the posterior wall of the pharynx.

PROGNOSIS AND COMPLICATIONS OF ADENOID VEGETATIONS.—Although these growths have a marked tendency to disappear at or shortly after the time of puberty they may yet exercise a most harmful influence. They are always a serious menace to the ears, since obstruction of the Eustachian tubes with consequent deafness and inflammation of the middle ear, purulent or non-purulent, are very prone to result. Catarrhal conditions of the nose, pharynx, larynx, and lungs are at all times liable to be induced by the presence of these growths; and various infectious diseases, chiefly scarlet fever, diphtheria, and measles, are far more dangerous and more likely to be attended by grave complications in children who suffer from post-nasal vegetations. Moreover, these growths undoubtedly produce deformity of the chest, and arrest not only the physical development of the child, but also its mental progress—probably in large part owing to the deafness they occasion. It is beyond question that 99 out of every 100 children from whom adenoid vegetations have been removed improve markedly in every way within a few weeks after the operation.

TREATMENT.—Palliative treatment is of little value. The nasal spray may be used twice or thrice daily to clear away the muco-pus which is commonly present, and thus by reducing any catarrhal inflammation to slightly increase the airway in the naso-pharynx. The only reliable treatment is removal of the growths, and this is essential in all cases in which any aural or respiratory com-

plications (e.g. deafness, pain in the ear, recurring attacks of bronchitis) exist.

An anæsthetic is, in this country, almost always administered. In infants it is perhaps best dispensed with. Chloroform should, in the writer's opinion, never be given, most of the few deaths having occurred in cases in which this anæsthetic was administered. It must be borne in mind that anæsthesia introduces an element of danger into an operation otherwise devoid of risk. For the removal of adenoids alone nitrous-oxide gas with or without admixture with oxygen suffices for a fairly rapid operator, and is the safest of all anæsthetics. If, as frequently happens, hypertrophied tonsils demand removal at the same time, the A.C.E. mixture answers admirably. The best position is with the patient lying on the right side with the head supported by the anæsthetist or assistant beyond the end of the table, and kept about an inch lower than the rest of the body, the face being turned slightly downwards. In this position blood runs freely out of the mouth and nose and cannot enter the larynx. The removal of the growths may be accomplished by means of cutting forceps, of which Löwenberg's forceps, or one of the modifications of this instrument, may be used, but most operators prefer Gottstein's curette. For softish growths this instrument leaves nothing to be desired; for a firm adenoid tumour in an older patient it is often necessary to punch several pieces out of the mass before curetting. Scrupulous care must be taken to ensure all instruments used being sterile. Hæmorrhage is frequently alarming for a few seconds, but rapidly stops spontaneously. Fatal hæmorrhage is almost unknown. Most patients require no after treatment, except perhaps a laxative on the second or third day after the operation. In a small proportion of cases the operation may be followed by some febrile disturbance with swelling of the cervical glands, acute otitis media, or acute tonsillitis, but these accidents can generally be prevented by sterilising the instruments employed. Recurrence to a slight extent is frequent, but, except in very young children under three or four years of age, the surgeon can as a rule promise confidently that no recurrence sufficient to call for a second operation will take place.

The results of the operation are, as above indicated, almost invariably excellent, the deafness and otorrhœa, if present prior to the removal of the growths, rapidly disappear, speech and nasal respiration become normal, and the physical and mental development of the patient improves to a remarkable extent.

6. **Syphilis** may attack the nose in almost any part, and may affect bone, cartilage, skin, or mucous membrane, or any combination of these. The condition may be due to hereditary syphilis or to the acquired form in any of its stages.

Hereditary Syphilis attacks primarily the mucous membrane of the nose. It is met with in infants a few days or weeks old in the form of 'snuffles,' a catarrhal inflammation of the nasal mucosa, the discharge from which soon becomes muco-purulent or purulent. The swelling of the nasal mucosa with formation of crusts obstructs nasal respiration, especially in suckling and during sleep. If not efficiently treated the inflammatory process may spread to the bones and seriously deform the nose. This accident is, however, far more apt to occur in those cases in which the nose is attacked about the

period of puberty. In this delayed hereditary form of nasal syphilis the commencement of the trouble is also a rhinitis with muco-purulent or purulent discharge and much obstruction to nasal respiration. After some days or weeks the discharge (in untreated cases) becomes blood-stained and foul (so-called syphilitic ozæna), and the bones of the nasal chambers become involved in an osteo-periostitis, which leads to necrosis, which may at times be most extensive. The nasal bones, the vomer, inferior turbinals, and palatal processes of the maxillæ are those most frequently affected; and when the two first-mentioned suffer the nose is apt to be characteristically sunken and deformed.

Acquired Syphilis.—*Primary chancres* of skin or mucous membrane are exceedingly rare if we except those situated around the orifice of the Eustachian tube, due to catheterisation with infected instruments. The diagnosis of these chancres of mucous membrane is rarely made with certainty prior to the appearance of secondary symptoms.

In the *secondary* stage mucous patches (*plaques muqueuses*) are met with on the nasal mucous membrane almost always in association with others in the mouth, fauces, tongue, vulva, or anus. They appear as little superficial erosions which may be hidden by overlying scabs; and not infrequently they form a ring around the margin of the nostril and may block the orifice. The process does not extend deeply and never involves the periosteum or bones of the cavities of the nose. The diagnosis is confirmed by the discovery of other syphilitic phenomena.

Tertiary syphilitic lesions of the nose are common and destructive, and often leave behind them serious deformity. They are chiefly observed four years or more after the appearance of the chancre, attack primarily the bones, and, as a rule, involve the mucous membrane subsequently. The bony lesions are in general a combination of necrosis and caries. The bones most frequently attacked are the vomer, the nasal bones, and the upper surface of the palatal processes of the maxillæ. Gummatous destruction of the septal cartilage is likewise very common. The symptoms are at first indefinite. Soon, however, complaint is made of stuffiness in the nose, and of blood-stained fetid purulent discharge, the odour of which is (unlike that in true ozæna) disagreeably manifest to the patient. Frequently small particles of dead bone can be found in the nasal discharge. After cleansing the nose with a spray, an examination reveals the presence of crusts partly covering ulcerated surfaces of mucous membrane, sloughs of greyish or purplish hue, and frequently of bare sequestra of bone, generally much darkened or even black in colour. The above represents a severe and advanced stage of the disease. In an earlier stage, before necrosis has occurred, the gummatous infiltration may be absorbed by appropriate treatment and leave little or no trace of its presence. Should the ethmoid bone be attacked, as rarely happens, the condition is most grave, as septic meningitis is apt to develop. In general after the casting off of several small sequestra, a tendency towards healing, even in untreated cases, is apt to manifest itself; in rare instances, however, particularly in debilitated drunkards, the destructive process may advance with terrible rapidity and involve several of the bones of the face, giving rise to a huge chasm with hideous deformity. Frequently the deformity is increased owing to multiple

gummatous formation and ulceration in the skin covering the nose and cheeks.

TREATMENT.—Primary and secondary lesions in acquired syphilis and snuffles and other early hereditary symptoms require a prolonged mercurial course. In cases in which there is abundant formation of crusts and in which the erosions are spreading, the former may be removed after softening them with an ointment composed of Unguent. hydrarg. nitratis, 15 grains, or of Hydrarg. oxidi flav. 10 grains, to the ounce of vaseline, and the raw surface of the erosion touched with a 2-per-cent. solution of chromic acid in distilled water, or with a solution of perchloride of mercury (1 to 1,000).

In tertiary nasal syphilis, and in late hereditary manifestations, the best results are obtained by the combined administration of mercury and iodide of potassium; the latter drug must in most cases be given in full doses—15 grains to 30 grains thrice daily to adult patients. The other indications are to wash away with a mild antiseptic spray the blood-stained purulent discharge and to remove any loose sequestra of bone. In addition, particularly in late hereditary manifestations, it is frequently wise to administer tonics and cod-liver oil.

7. Tubercular Disease.—Tuberculosis attacks the nose in two very different forms, (a) Lupus, (b) Tubercular disease of mucous membrane. These two conditions, though both caused by the tubercle-bacillus, demand separate description.

(a) *Lupus.*—Lupus affecting the external aspect of the nose is described in the articles LUPUS ERYTHEMATOSUS; and SKIN, Tuberculosis of. Lupus of the nasal mucosa is generally an extension of the disease from the skin, and is rarely a primary condition. It is chiefly met with in young subjects and occurs chiefly in the region of the cartilaginous septum, inferior turbinates, and anterior part of the floor of the nose. It may not infrequently be seen on the upper surface of the soft palate and in the naso-pharynx. The symptoms are at the beginning quite slight, complaint being generally made of stuffiness in the nose and scab-formation. On examination several tiny nodules varying in size from a millet-seed to a hemp-seed are observed; they are generally discrete, superficially ulcerated, and in part covered by crusts. Frequently perforation of the septum is found, the margins of the orifice being surrounded by flabby granulations. The diagnosis is rendered easy by the almost invariable co-existence of lupus of the skin. The progress of the condition is essentially chronic, lasting several years. The bones of the nose are never attacked, necrosis being therefore unknown. This is an important point in the differential diagnosis of lupus and syphilis, though it must be remembered that the two conditions may be found together. The treatment of lupus of the nasal mucosa must be thorough. General treatment (cod-liver oil, iron, tonics, &c.) is necessary, but it is upon local treatment that the chief dependence must be placed. All the diseased tissue must be freely destroyed, preferably by curetting with a small sharp spoon and then applying either a bead of chromic acid or lactic acid (50-per-cent. solution or undiluted). Any small recurrences, which are very apt to form, must be treated in a similar way. The electric cautery is frequently used, but the writer employs it only after a thorough preliminary curetting. The results of this treatment are frequently excellent.

(b) *Tubercular Disease of the Nose* is distinctly rarer than lupus. Usually it is secondary to tuberculosis of the lungs or larynx. Only very rarely is it primary, in which case it generally assumes the form of an irregular, nodular, pedunculated tumour, which is friable and bleeds on the slightest contact, and grows from the septum nasi in a person otherwise in good health. Soon this mass begins to ulcerate, becomes partly hidden by scab-formation, and eats a hole in the septal cartilage. Glandular enlargement in the neck and submaxillary region then follows. Tubercular ulceration, secondary to disease of lungs or larynx, is much more common. It is found generally in the last stages of phthisis, and may attack any part of the nasal mucosa, though most commonly its site is on the septum and floor of the nose. The ulcers may be single or multiple, and vary from the size of a split-pea to that of a florin. Their margins are irregular, excavated, and surrounded by a ring of little tubercles in various stages of formation or of ulceration. Their bases are covered with muco-purulent secretion or sloughs, and present a yellowish-grey or reddish-grey colour. The progress of such ulcers is slow, and perforation of bone or cartilage is common.

DIAGNOSIS.—In the secondary (ulcerative) type no difficulty is encountered owing to the co-existence of phthisis (pulmonary or laryngeal). In tubercular tumour (the primary form) the recognition of the case is frequently extremely difficult. Syphilitic disease, sarcoma, and epithelioma have to be excluded—the first of these by the failure of anti-syphilitic treatment. The diagnosis may in certain cases be made by the microscopical examination of a portion of the growth, or by finding tubercle-bacilli; but where the diagnosis rests between tuberculosis and malignant disease it is wise in general to remove the growth first and ascertain its exact nature afterwards.

TREATMENT.—(1) *Of Tubercular Tumour.*—This consists in encircling the pedicle with the galvanic-caustic snare, and in thoroughly curetting its base. After curetting lactic acid (50-per-cent. solution) must be well rubbed into the raw surface, or iodoform dusted over it.

(2) *Of the Secondary Ulcerative Form.*—Here the treatment can be only palliative, especially when the ulcers are multiple and the phthisis advanced. Mild antiseptic nasal sprays with insufflation of iodoform alone, or mixed with boric acid (1 to 4), may be used. If the ulcer is solitary and the general condition fair, lactic acid may be applied (50 per cent.), after curetting the ulcer. Healing of these secondary tubercular ulcers, however, the writer has never seen.

8. Affections of the Septum Nasi.—The chief affections of the nasal septum are: (1) Deviations and Spurs; (2) Hæmatoma; (3) Abscess; and (4) Perforating Ulcer.

(1) *Deviations and Spurs.*—A perfectly vertical nasal septum is exceptional in the adult though the normal condition in the young child. The cartilaginous portion is commonly the part most deflected, the hinder bony margin of the septum being in general quite vertical. The septum may present a general convexity on one side and a corresponding concavity on the other side; or the deviation may be of the sigmoid type, in which the deflection is towards one side below and anteriorly, and towards the opposite side above and posteriorly.

Spurs of the septum are of two kinds—linear

ridges (crests), and the much rarer conical spines. Both varieties are usually found in or about the line of junction of the vomer with the septal cartilage. They are frequently observed along with deviation of the septum nasi, and consist chiefly of cartilage, though some bony substance is often present in their interior. The symptoms to which they give rise are dependent in large measure upon the degree of obstruction to nasal respiration which they occasion. Slight deviations and spurs produce no symptoms, and call for no treatment. Where, however, they are of large size they tend to produce obstruction, and chronic nasal catarrh with associated affections of the Eustachian tube and middle ear. Sometimes a conical spine presses against the anterior portion of an enlarged inferior turbinal bone and causes ulceration, hæmorrhage, or even suppuration.

TREATMENT.—Cauterisation of the inferior turbinal body with the galvano-cautery, by causing shrinkage of its hypertrophied mucosa, will, in many instances, be found effectual in relieving the symptoms, and should in the majority of cases be given a fair trial prior to resorting to more severe measures. When, however, it is necessary to remove the projecting part of the septum (summit of convexity) or a crest or spine, the mucous membrane covering the prominence is to be incised in a direction from behind forwards, and then the projection sawn off by means of a Bosworth's nasal saw. When the deviation is of the sigmoid type the lower convexity is alone to be attacked, the upper one being as a rule out of reach and not much of an obstacle to nasal respiration.

(2) *Hæmatoma of the Septum.*—Owing to the fact that the mucous membrane covering the nasal septum is not firmly adherent to the cartilage and bones, it is very readily detached from these structures by an effusion of blood. In certain cases a unilateral hæmatoma may be found as the result of some injury associated with sudden twisting of the septal cartilage. More frequently we have to deal with a bilateral hæmatoma, which is always the result of a fracture of the cartilage or one of the bones of the septum. A hæmatoma presents itself as a purplish red swelling on one or both sides of the cartilaginous septum, just inside the nostrils, with a broad base and a distinctly fluctuating elastic feel. In bilateral cases pressure on the one side causes collapse on that side, and an increase in the prominence on the opposite side of the septum. As a rule no treatment is required beyond attending to the fracture (if one be present) of the septum. Should, however, the swelling be of great size, and suppuration threaten, an incision may be made on each side through the mucous membrane; the blood, clot, or blood-stained serum evacuated, and the pockets washed out with an antiseptic solution, e.g. biniodide of mercury, 1 to 2,000. This small operation should be preceded by antiseptic irrigation of the nose, and followed by plugging the nostrils with strips of double-cyanide or iodoform gauze.

(3) *Abscess of the Septum.*—Acute abscess is commonly the result of the suppuration of a hæmatoma. A more serious variety is that of lymphatic origin secondary to a boil in the region of the columella nasi. The former is generally bilateral, the latter unilateral. The symptoms are those of nasal obstruction, and fever with redness and swelling of the nose.

Chronic abscess may be due to necrosis of bone or cartilage the result of traumatism, syphilis, or

tuberculosis; or may be found as a complication of small-pox, typhoid, or other specific fever.

TREATMENT.—An acute abscess requires incision and antiseptic irrigation. A chronic abscess demands in addition curetting and removal of necrotic portions of bone or cartilage. It is apt to leave behind a perforation of the septum.

(4) *Perforating Ulcer of the Septum.*—Apart from perforation of the septum due to syphilis or tuberculosis, there occurs also a slowly progressive circular ulcer situated just within the nostril first described by Jonathan Hutchinson, and known as 'perforating ulcer of the septum.' The process starts in the mucous membrane covering the septal cartilage; a grey sloughy false membrane appears and is cast off, and the denuded cartilage is slowly eroded. The ulcer usually perforates the septum, but rarely it stops short and cicatrises. When the perforation is complete and the margins of the hole have healed, the opening is so wonderfully regular and clean cut that it has been thought to be of congenital origin. Of the true pathology of perforating ulcer little is known. Workers in chromic acid are peculiarly liable to suffer from it. Symptoms may be absent, and the patient may be unaware of the fact that his septum is diseased or perforated. Generally there is a feeling of irritation which leads to scratching and picking the surface of the ulcer. Epistaxis is not infrequent. When the ulcer has perforated, healing of the margins of the perforation generally occurs, but the aperture in the septum does not close.

Treatment consists in spraying the nose with a warm solution of bicarbonate of sodium and borax (of each 3j to water ʒviij) to remove the crusts, and in cauterising the ulcer (after applying a 10-per-cent. solution of cocaine) with the acid nitrate of mercury or the galvano-cautery. Thereafter an ointment consisting of Hydrarg. oxid. flav. or iodoform, ʒss to the ounce of lanoline, may be employed.

9. **Foreign Bodies in the Nose** are very frequent in children, in hysterical women, and in the insane. Among those which are most common may be mentioned peas, beans, glass-beads, pieces of slate-pencil, cherry- and plum-stones; these are almost always introduced by the patient through the anterior nares. A foreign body (e.g. a particle of food) may also be forced into the nose through the posterior nares in the act of vomiting. Sometimes a detached and loose sequestrum plays the part of a foreign body. Foreign bodies introduced by the anterior nares are commonly found situated on the floor of the nose or under cover of the inferior turbinal, while those vomited into the nose are most frequently seen in the middle meatus. The presence of a foreign body generally produces after an interval of time an offensive muco-purulent or purulent discharge commonly tinged with blood; and symptoms of nasal obstruction are manifested. Much depends on the nature of the foreign body: thus while a pea or bean swells very soon by imbibition of fluid, and may even sprout, a glass bead will produce symptoms much more slowly. The discharge is intensely foetid and irritant, causing frequently an eczematous condition of the skin of the upper lip and around the aperture of the nostril. The discharge is necessarily unilateral; and in every case of unilateral nasal discharge occurring in a child, especially if it be foetid, the presence of a foreign body should be suspected.

The treatment consists in spraying the nose with

a 1-per-cent. solution of cocaine, and removing the foreign body. Forceps should not as a rule be used to seize the object, as they are apt to miss their hold and to shoot the foreign body further into the nose. A small hook, or a probe of which the last one-third of an inch is bent to a right angle with the rest of the instrument, is to be insinuated behind the foreign body, which may then be easily withdrawn. Its removal suffices for the cure of the symptoms, but a mild antiseptic nasal spray may be given to cleanse the nose.

Rhinoliths.—Calculus concretions are occasionally found in the nose. They invariably originate round a foreign body or a plug of inspissated mucus. They consist largely of phosphate and carbonate of lime, and give rise to the same symptoms as a foreign body. The resulting purulent rhinitis tends to further deposition of calcareous matter, and thus the rhinolith increases in size. The treatment of rhinoliths is removal. In cases of small nasal stones this is easy enough, but large rhinoliths may require to be crushed *in situ*; or it may be necessary to detach the ala of the nose to facilitate their removal. In other cases they may be pushed back into the pharynx and thus removed. Care should, however, be taken in such cases, especially when an anæsthetic is administered, that the foreign body is not allowed to fall into the larynx. See p. 335.

10. Parasites in the Nose.—In this country they are exceedingly rare, but in hot climates various species of flies, attracted sometimes by the odour of decomposition in cases of *ozæna*, gain entrance to the nose and there lay their eggs. The warmth and moisture ensure that these are hatched, and the maggots swarm all over the nose and accessory cavities, and may destroy the mucosa and even cause necrosis of the bones, and frequently death. Earwigs, leeches, the *Oxyuris vermicularis*, and the *Ascaris lumbricoides* are occasionally found in the nasal passages, and also the larvæ of the common bluebottle. The treatment consists in irrigation of the nose with antiseptic solutions or the introduction of chloroform-vapour into the nose. Both these methods have for their object the destruction of the maggots, but it is obviously a matter of extreme difficulty to ensure that all these are destroyed in the accessory sinuses of the nose.

11. Rhinoscleroma.—This condition, first described by Hebra in 1870, is practically unknown in Great Britain. It is chiefly met with in the eastern districts of Austria, in Southern Russia and in Central America. It is to be grouped with the infective granulomata, and is characterised by the formation of exceedingly hard nodular thickenings in the skin and mucous membrane of the upper respiratory passages. In more than 90 per cent. of all cases the nose is attacked. The nodules are either discrete or diffuse. They are painless, and vary in colour from that of the normal skin to a dusky red hue. Their surface is smooth and shining, and they tend to invade the tissues in their vicinity both superficially and deeply. The condition, which is quite incurable, lasts for years, and other parts besides the nose become infected, chiefly the palate, pharynx, upper lip, maxilla, and larynx. Ulceration is very rarely seen. The nodules on histological examination show chiefly large round cells (much like those of a round-celled sarcoma), and in them is always to be found a short, thick bacillus (*Bacillus* of Frisch) which is undoubtedly

the cause of the disease. Retrogressive changes occur in the nodules, resulting in the formation of cicatricial connective tissue. Thus the infiltrated parts become markedly contracted, and stenoses of nose, pharynx, and larynx are produced. The cartilaginous induration and brawny thickening of nose and upper lip, and the nasal and frequently laryngeal stenosis, along with the entire absence of ulceration, distinguish rhinoscleroma at once from lupus, malignant disease, and syphilis. Prognosis is hopeless, a cure being unknown. Treatment is seldom of any service except for laryngeal stenosis, when tracheotomy will prolong life. Interstitial injections of antiseptic solutions, the rubbing into the affected parts of a 1-per-cent. solution of corrosive sublimate in lanolin (Doutrelepoint), the thermocautery or the sharp spoon have all been advocated.

12. Nasal Diphtheria.—Diphtheria affecting the nose is described in the article on DIPHTHERIA. In this place it will suffice to draw attention to the fact that a sanious diphtheritic discharge from the nasal cavity or a diphtheritic membrane on its mucous surface may exist without any severe constitutional symptoms.

13. Tumours of the Nose.—The commonest tumours of the nasal chambers are myxomata and fibro-myxomata, which almost always tend to assume a polypoid shape. Less frequently there occur angiomata, adenomata, osteomata, enchondromata, and malignant neoplasms, epitheliomata and sarcomata.

Myxomata or *Mucous polypi* are very soft, gelatinous and almost translucent in appearance. Their colour is whitish-grey, with a faint blue or pink tint. They are, when of any size, generally pyriform and pedunculated, more rarely sessile. They vary in size from that of a hemp-seed to that of a plum, and are commonly multiple. Their most frequent site of attachment is the lower border of the middle turbinated bone; less frequently they grow from the superior turbinated bone and superior meatus. Very rarely they spring from the septum and inferior turbinated body, and never from the floor of the nose. They may arise in the interior of the accessory sinuses, and may grow backwards into the naso-pharynx, where they may attain large dimensions. The cause of mucous polypi is most uncertain, though it is probable that affections of the accessory sinuses, around the orifices of which they are most commonly situated, play a part in their production. The tumours consist of gelatinous myxomatous tissue containing a varying amount of fibrous stroma, with few vessels and no nerves. They are commonly covered externally with ciliated epithelium.

SYMPTOMS.—At first these are slight, complaint being made of nasal obstruction, and a feeling of fulness in the head, aggravated in damp weather, as the polypi are very hygroscopic. There is an excessive secretion from the nostrils, which is at first mucous but becomes later muco-purulent or even purulent; epistaxis is not uncommon. Reflex disturbances are prone to occur, the commonest being asthma, hemicrania, neuralgia and cough. When the polypi completely block the nose the latter becomes broadened and total loss of smell with dryness and irritation of the pharynx result.

TREATMENT.—Removal of the polypi is the only efficient treatment, and this is to be followed by cauterisation or curetting of their divided pedicles in order to prevent recurrence. Avulsion with

polypus-forceps is a rude and obsolete method. Either the cold snare or the galvano-caustic loop may be used. In all cases the instrument must be guided by the sense of sight, and a solution of cocaine must be previously employed, preferably in the form of a spray. Cocaine has the triple advantage of deadening pain, causing shrinkage of the neighbouring hypertrophic and hyperæmic mucosa, and lessening the hæmorrhage. The cold wire-snare is the best instrument to use in the case of large polypi. Its employment must be followed by the curettage or the destruction of the base of attachment by the application of the galvano-cautery or of chromic acid. For smaller and very numerous polypi the galvano-caustic snare answers best. It has the advantage that it destroys the pedicles of the polypi, but adhesion between the turbinal body and the septum nasi is apt to follow its use. In bad cases several sittings will be required before every particle of myxomatous tissue can be destroyed. The after-treatment consists in the employment of a mild alkaline nasal spray.

Angiomata of the nose are very rare tumours, of a bluish-red or violet colour, which grow from the septum nasi or upper (olfactory) portion of the nose. They produce nasal obstruction and severe epistaxis. They have a broad base of attachment and an irregularly mammillated appearance, and frequently pulsate. They must not be confounded with mucous polypi. Such a mistake might give rise to profuse hæmorrhage after removal. The treatment is destruction with the galvano-cautery or removal by means of the galvano-caustic snare. If the latter be used it is to be employed at a dull-red heat, and constriction is to be very gradually applied.

Adenomata.—Rarely tumours composed of glandular (mucous gland) tissue are found in the nose. They are of firmer consistence than the mucous polypi, and merge into the surrounding hypertrophic mucosa. The galvano-cautery or galvano-caustic snare must be employed for their destruction or removal.

Chondromata are rare apart from cartilaginous outgrowths or spurs on the inferior and anterior part of the nasal septum (echondromata). These latter are described under affections of the septum nasi. True cartilaginous tumours (enchondromata) may grow from the septum or roof of the nasal passages in children and young adults. They obstruct nasal respiration and cause a muco-purulent blood-stained discharge. If operable at all they demand a formidable operation for their removal, and recurrence of the growth is very frequent.

Osteomata.—Apart from exostoses forming spurs and crests of the septum nasi, which have been already described, tumours composed of bony tissue—sometimes of cancellated but more frequently of ivory compact bone—are met with in the nasal passages and accessory sinuses; they are, however, uncommon. In shape they are generally round or oval, and they sometimes perforate the walls of the bony cavity in which they originate. Until they attain a considerable size they give rise to no symptoms. In their growth, however, by pressure upon neighbouring structures they cause severe neuralgic pains, a feeling of nasal obstruction, ulceration of the mucous membrane that covers them, and thus a hæmorrhagic or purulent discharge which may be foetid. Removal of these tumours is the only effectual treatment. The rarer cancellous forms are

readily removed by means of forceps or a fine saw. The ivory osteomata, particularly when situated in the upper accessory cavities, ethmoidal, frontal or sphenoidal, can, in many cases, only be removed by operations which open or injure the dura mater, and are therefore scarcely justifiable. When growing from the lower two-thirds of the nasal passages or from the antrum of Highmore their removal can be in general safely accomplished.

Papillomata.—True papillomata of the nose are of infrequent occurrence, and must not be confounded with papillary hypertrophy of the mucous membrane covering the inferior turbinal body, which is a far more common condition. Their usual seat of origin is the cartilaginous part of the nasal septum or the floor of the nasal fossa. They are to be snared with the galvano-caustic loop or destroyed by the galvano-cautery.

Malignant Tumours.—Primary malignant tumours of the nasal passages are fortunately rare. The varieties which are met with are (1) epitheliomata and (2) sarcomata. Malignant neoplasms originating in neighbouring parts and involving the nose by extension are much more common.

Epitheliomata are rare as primary tumours, and may be composed of squamous or columnar epithelium. They originate either in the mucous membrane covering the septum or the turbinal bodies, and the course of such growths is at the commencement slow, then after a time it becomes very rapid. The destructive process eats away nose, septum and palate, and gives rise to a horrible chasm in the centre of the face. Rapidly developing cachexia and death supervene.

Sarcomata generally commence in the septum as chondro-sarcomata or fibro-sarcomata. The former variety is sometimes seen in young children, but sarcomata are more frequent in the aged. Malignant tumours of the nose cause frequent epistaxis, foul blood-stained discharge, loss of smell, and rapid wasting. The prognosis is very bad, their removal is always difficult, and in the upper parts of the nasal passages often impossible, owing to infiltration of the cranial bones. Even after apparently free removal recurrence is the rule. In many cases the cautery may be used for their destruction or removal in preference to any severe operation on the bones of the face.

Tumours of the Naso-Pharynx.—(1) *Naso-pharyngeal Fibrous Polypi*.—These tumours are usually composed of almost pure fibrous tissue, sometimes mixed with myxomatous or cellular elements. They are generally covered by an unbroken mucous membrane, and spring by a broad base from the periosteum covering the base of the skull, particularly from that of the basilar process of the occipital bone and the body of the sphenoid. These fibrous polypi of the naso-pharynx are dense, very hard, often lobulated tumours, of great vascularity, and frequently of great size; they are met with most frequently in young male adults. If not removed the mass displaces the bones in the neighbourhood, which may become eroded, and sends large processes into adjacent cavities—e.g. cranium, orbit, and zygomatic fossa. These tumours have a distinct tendency to degenerate into sarcomata.

TREATMENT.—Removal of the tumour is urgently called for, but in large growths the ablation of the mass is a very serious operation, owing to the severe hæmorrhage generally encountered, and the difficulty of gaining access to the pedicle.

Smaller growths may be removed by means of the galvano-caustic snare used very deliberately. Larger growths require either as a preliminary to their removal splitting of the soft palate, which gives generally insufficient access to the growth, or Langenbeck's osteo-plastic resection of both upper jaws.

(2) *Fibro-myxomatous* or purely *Myxomatous Polypi* are occasionally found in the naso-pharynx. These growths have their origin in the nasal passages, and spring from the hinder extremities of the turbinal bodies, or from the septum. They fall backwards into the naso-pharynx, and are therefore sometimes erroneously considered to be of naso-pharyngeal origin. They are readily removed by the galvano-caustic loop.

14. **Affections of the Accessory Nasal Sinuses.**—The maxillary (Antrum of Highmore), ethmoidal, frontal and sphenoidal sinuses are subject to morbid changes, sometimes arising primarily, but far more frequently secondarily, to affections of the nasal fosse.

(a) *Frontal Sinus.*—Injuries to this sinus are frequent as the result of direct violence. Fracture of the outer wall of the sinus is apt to be accompanied by emphysema of the neighbouring soft parts. Compound fractures, which involve the inner wall of the sinus and lay bare or even lacerate the dura mater, are, of course, formidable injuries. Not infrequently they are complicated, and caused by the presence of a foreign body. Operative interference is, of course, demanded to remove the foreign body, and to purify the interior of the sinus. Not very infrequently, particularly in tropical countries, insects gain access to the interior of the nose, and lay their eggs in the frontal sinus; when the young are hatched they are apt to give rise to violent inflammation and suppuration in this cavity.

Inflammation of the frontal sinus is either acute or chronic, and most commonly results from extension of inflammation from the mucous membrane of the nose (in chronic cases this is generally syphilitic or tubercular in origin) from the bone or periosteum. The symptoms of acute inflammation of the frontal sinus are pain—often unilateral and generally radiating upwards and outwards, along the inner two-thirds of the eyebrow—headache, and a feeling of fulness and distension in the frontal bone with swelling and tenderness to the touch. When suppuration has occurred there is dusky discoloration of the skin overlying the cavity.

Suppuration (empyema) of the frontal sinus may be a sequel of acute inflammation, or may result from long-standing distension of the sinus with mucus, when the outlet into the middle meatus of the nose is obstructed. In chronic cases of empyema of the frontal sinus changes are apt to occur in the bony walls of the cavity, the floor of which often bulges into the orbit, displacing the eyeball. In extreme cases the bony wall becomes perforated, and the pus escapes into the orbital or cranial cavities, or into the nose.

TREATMENT.—In the early stages local blood-letting (e.g. leeching) will be beneficial; and when, as is usually the case, the inflammation of the frontal sinus is secondary to some nasal condition, treatment directed to this latter must be at the same time adopted. When pus-formation is demonstrated by the marked increase in the severity of the symptoms evacuation of the purulent contents of the sinus

must be at once undertaken, owing to the risk of cerebral or orbital complications. Evacuation of the pus by operating through the nose by way of the infundibulum is unsatisfactory and dangerous. In all cases it is best to operate from the forehead, and this can be done with a minimum of disfigurement by making the incision in the line of the eyebrow, which has been previously shaved. The sinus is then perforated by a small trephine, and a small drainage-tube passed through the infundibulum into the nose. Through this tube the cavity may be washed out.

Tumours are not infrequently found in the frontal sinus. Those most commonly met with are osteomata, fibromata and myxomata, among innocent tumours, and sarcomata and carcinomata. They call for removal by external incision, and in the case of malignant neoplasm a large amount of the frontal bone may require to be ablated.

(b) *Ethmoidal Sinuses.*—Affections of these sinuses are much less frequent than is the case with the frontal sinus. Still empyema, myxomatous tumours, and caries or necrosis which may give rise to septic meningitis, may be met with.

(c) *Sphenoidal Sinus.*—The affections of this cavity are very similar to those of the ethmoidal sinuses, and the symptoms in the two cases are practically identical. On account of the proximity of the sinus to the great vessels (internal carotid artery and cavernous sinus) caries and necrosis of the bony walls of the cavity are liable to give rise to fatal hemorrhage and septic sinus-thrombosis.

(d) *Maxillary Sinus or Antrum of Highmore.*—The commonest affection of the maxillary sinus is undoubtedly empyema, which may be the result of extension of inflammation from the nasal cavity or from the roots of one of the upper teeth, the fangs of which not uncommonly perforate the bony floor of the antrum.

The symptoms of antral suppuration are tenderness on pressure over the cavity and facial neuralgia; sometimes oedema of the overlying soft tissues; and in chronic cases with occlusion of the orifice of the antrum distension of the cavity, leading it may be to egg-shell cracking when pressure is made over the bone. A sign, that is when present diagnostic, is the sudden discharge of a considerable amount of pus from the nose when the head is held in a certain position, generally with the opposite side of the face resting on a pillow. Examination of the nose shows that the pus proceeds from under cover of the middle turbinated bone. It must be borne in mind, however, that this symptom is absent in the not infrequent cases in which the orifice of the antrum is obstructed. The purulent discharge from the antral cavity is in general fetid. Transillumination of the antrum in a dark room by means of an electric lamp held in the mouth with the lips tightly closed is a valuable guide to the diagnosis of antral empyema, the dark shadow on the affected side being in marked contrast with the translucent brightness on the normal side of the face. This is best seen in the region of the roof of the antrum, i.e. the floor of the orbit. Cystic degeneration of the antrum, neoplasms and marked thickening of the lining of the cavity may, however, cause the same opacity to transillumination.

When inflammation of the mucous lining of the antrum comes under observation before pus-formation has occurred, hot fomentations, local blood-letting and appropriate treatment of any causal

nasal affection will be employed. As soon as pus has formed, particularly in cases in which the antral orifice is blocked, it must be removed. The antrum may be perforated (1) through the socket of a diseased upper molar or bicuspid tooth, (2) through the outer wall of the cavity, or (3) through the inferior meatus of the nose by directing the trocar outwards through the inner (nasal) wall of the antrum. A drainage-tube is placed in the cavity, which is to be irrigated frequently; and if it be found blocked with polypi or granulation-tissue time will be saved by curetting such away. Drainage must be efficiently maintained until all purulent discharge has ceased. In cases of pus-formation in the antrum in which the antral orifice remains patent careful irrigation by means of a nozzle introduced into the antrum through the nose may suffice to cure the affection. The removal of the anterior segment of the middle turbinal bone renders the introduction of the irrigating nozzle much more easy.

Tumours of the antrum are not infrequent: 70 per cent. are malignant, sarcomata and carcinomata being nearly equally common. Osteomata, myxomata, fibromata, and cystic tumours also are not unusual. Innocent tumours may be removed after ablation of the outer bony wall of the cavity; malignant tumours demand excision of the upper jaw and are of very bad prognosis.

15. Reflex Nasal Neuroses.—While there can be no doubt that treatment applied to the interior of the nose does in some cases markedly relieve or even permanently cure certain conditions mostly affecting the respiratory passages, it must be admitted that the exaggerated statements put forward by some rhinologists explain, if they do not entirely justify, the scepticism entertained by the profession regarding the connection between diseased conditions in the nasal passages and other affections.

In the large majority of instances, but by no means in all, it will be found that nervous exhaustion or neurasthenia or hysteria will be found to play an important part in the production of the nasal neurosis, and that either hyperæsthesia of the nasal mucosa or erectile swelling of the turbinated bodies will commonly be present. Space only admits of mention being made of some of the more important morbid conditions which may be relieved or even cured by intra-nasal treatment.

Asthma.—Not infrequently polypi, hypertrophic rhinitis, morbid conditions of the inferior turbinated bodies, and more rarely deformities of the septum nasi, are found in patients suffering from bronchial asthma; and relief—most frequently only partial, but in some instances total and permanent—of the asthmatic affection has followed treatment directed to the removal of the nasal condition.

Paroxysmal Coughing and Sneezing are apt to be induced by hypertrophic and diseased conditions, particularly of the inferior turbinated bodies, and to cease after appropriate treatment, e.g. cauterisation.

Headache, Neuralgia of the Fifth Nerve, Megrin and Spasmodic Closure of the Glottis are in rare cases much benefited by intra-nasal treatment, and may therefore be considered as occasional reflex nasal neuroses; but epilepsy, vertigo, exophthalmic goitre, and many other morbid conditions (many of them of hysterical origin), have no claim to be considered as such. See PAIN IN VISCERAL DISEASE.

In connection with reflex nasal neurosis, mention must here be made of the interesting group of vasomotor coryzas, of which the best known examples are hay-fever (see HAY-FEVER), rose-fever, and rhinorrhœa, which last has already been described in this article.

HERBERT F. WATERHOUSE.

NOSTALGIA (*νόστος*, return; and *ἄλγος*, sadness).—**SYNON.**: Fr. *Nostalgie*; Ger. *Heimweh*.—A form of melancholia, sometimes occurring in persons who have left their homes. The symptom from which it derives its name is an intense desire to return home; and this is accompanied by great mental and physical depression, which may end fatally. See MELANCHOLIA.

NUCLEUS.—See CELL.

NUMMULATED SPUTUM (*nummus*, a coin). A form of sputum which, when spreading out on a surface or floating in water, resembles a coin in shape. See SPUTUM, Examination of.

NURSING THE SICK.—Nursing is performed usually by women, under the direction of physicians and surgeons. Good nursing should put the sick under the best possible conditions for Nature to restore health and to cure disease or injury. The physician or surgeon prescribes these conditions—the nurse carries them out. Partly, perhaps mainly, upon nursing must depend whether Nature succeeds or fails in her attempt to cure. Nursing is therefore to help the patient to live. *Training* is to teach the nurse to help the patient to live. Nursing is an art, and an art requiring an organised, practical, and scientific training. For nursing is the skilled servant of medicine, surgery and hygiene.

Nursing may be divided under four heads: (a) *Hospital nursing*. (b) *Private nursing*: that is, nursing one sick or injured person at a time, at home; giving the whole time to that one patient, generally of the richer classes. (c) *District nursing*: that is, nursing the sick or injured poor at home, taking as many cases as can be well attended to by one nurse. District nursing, or nursing the sick poor at home, is a branch of nursing of the highest importance, and requires the highest qualifications, because the district nurse has not, like the hospital nurse, a medical and surgical staff always at her call, and never has hospital appliances to her hand. (d) *Midwifery nursing*, including the nursing of the healthy mother and infant after natural childbirth, the feeding, washing, and clothing of infants, and the teaching the mother the management of her own infant and herself, will not be treated of here; but it may be observed that midwifery and septic or infectious cases should not be attended by the same nurse. No ordinary precautions will secure the lying-in case from danger arising out of this practice.

Nursing proper means, besides giving the medicines and stimulants prescribed, or applying the surgical dressings and other remedies ordered—(1) The provision of fresh air in proper quantity without draughts (ventilation), especially at night, and the maintenance of a proper temperature. (2) Hygienic conditions in the sick-room or ward, which include light, cleanliness of floors and walls, of bed, bedding, and utensils. (3) Personal cleanliness of patient and of nurse, quiet, variety, sympathy, and cheerfulness. (4) The administration and sometimes preparation of diet (food and drink).

(5) The application of remedies. (6) Observation of the patient. We shall now discuss these duties in succession.

1. Ventilation. Warmth and Coolness.—

(a) *Ventilation* is the removal of the air poisoned by the breath and other human emanations, and supplying its place with *fresh* air.

The very first canon of nursing is to keep the air inside as fresh as the air outside, by night as well as by day, without chilling the patient. The best rule of ventilation is still: Poke the fire and open the window. Air should be admitted from the outside. Windows are made to open, doors are made to shut. If the nurse ventilate the patient's room or ward through the door—that is, make the room draw the foul air from the rest of the house or building—she supplies him with foul, not fresh air. But ventilation is impossible without sufficient floor and cubic space, and unless the windows open near the ceiling. All patients need a free supply of air without draughts, especially cases of infectious disease, the danger of spread being reduced in proportion as ventilation is free.

(b) *Warmth or coolness*.—This the physician has to prescribe—the nurse has to see to it. In fever, for instance, the physician will require her to examine the patient's feet and legs, at least every hour, to ascertain whether they are chilled, and to keep the extremities warm, even though his temperature be high, whether in summer or winter.

In bronchitis and in some other cases an even, high, moist temperature may be necessary, and a steaming kettle may be required on the fire night and day.

But ordinarily it is not advisable to keep the sick-room always at the same temperature. A cooler air at night is necessary. But whether cool or warm, the air must be *fresh*. Sick children become fretful in foul air at night. And young as well as old night-nurses require training to see that the physician's orders are obeyed as to keeping the air of the ward fresh by night, and not above or below a certain temperature. If warmth is obtained by means of an open fire, the nurse must replenish it noiselessly, without waking or disturbing the patient. For this purpose lumps of coal wrapped in damp paper may be kept ready.

The head of the sick person should never be higher than the throat of the chimney, which ensures the best air. And the chimney should never be closed with a chimney-board or other contrivance.

2. *Health of Sick-Room, or Ward*.—This might be called 'nursing the room.' The placing the sick-bed in the best position to secure air without draught, light without glare, quiet and cleanliness—and this often necessitates rearrangement of the furniture of the whole room—is one of the essential arts of nursing. In district nursing of the poor, it must be one of the nurse's first duties to put the room in a state so that the patient can recover. The hospital and the hospital-ward must be so built that the patient shall not 'die of hospital.' To get rid of the conditions which have interfered with health is of course the first step in helping Nature to get rid of the effects of those conditions.

(a) *Light*.—Second only to air is light as an essential for growth, health, and recovery from sickness—not only daylight, but sunlight—and indeed *fresh* air must be sun-warmed, sun-penetrated air.

This should be meant to include colour, pleasant and pretty sights for the patient's eyes to rest on—variety of objects, flowers, pictures. People say the effect is on the mind. So it is; but the enlightened physician tells us it is on the body too. The sun is a sculptor as well as a painter. The Greeks were right as to their Apollo.

(b) *Cleanliness*.—Cleanliness and fresh air do not so much give life as they are life itself to the patient. Cleanliness—clean air, clean water, clean surroundings, and a fresh atmosphere everywhere, are the true safeguards against 'infection'—not segregation—or rather segregation by ample floor and cubic space, ample ramparts of fresh atmosphere, not segregation by walls and divisions. You cannot lock-in or lock-out the infectious poison; you cannot wall-out infection. You *can* air it out, diffuse it, and clean it away.

Cleanliness of floors, ceilings, walls, bed, bedding and utensils, and of sinks; also of lockers, if any—but there should be none.

Floors and walls.—Medical men forbid scrubbing in the sick-room. No sick-room floor ought ever to be washed, except by the doctor's orders and at the hour he orders.

The best floor for cleanliness, except in institutions where specially non-absorbent materials can be used, is planed boards, saturated with 'drying' linseed oil, well rubbed in, stained (for appearance sake) not too dark, so as *not* to hide the dirt, and polished with beeswax and turpentine. The floor should be wiped with a damp cloth and dried with a floor-brush, or cleaned by a brush with a cloth tied over it. Anything offensive or infective spilt should be washed off *at once* with soap and water. Hospital-ward floors should be scraped and polished every fortnight by a *frotteur* and dry-rubbed by a man every day. The patients should be provided with slippers. There should be no carpet, of course, in a sick-room, except a piece of washing druggit by the bedside. A dirty carpet literally infects the room.

The only clean wall is one that is absolutely non-absorbent. Of ordinary materials oil-paint and glazed tiles are probably the best. From this you can wash the animal matters. These are what make a room musty. The worst wall is the papered wall. The next worst is the plastered wall. But the plaster can be made safe by frequent lime-washing and occasional scraping. The paper requires frequent renewing. A glazed paper gets rid of a good deal of the danger. But the ordinary bedroom paper is all that it ought not to be.

Furniture—as little as possible in the sick-room—should all be of polished wood, metal, or marble, kept clean by being wiped with a cloth wrung out of hot water.

Air can be soiled just like water. Air is always soiled where walls and carpets are saturated with animal exhalations. Dust consists largely of organic matter. There should be no ledges out of reach capable of holding dust. An Arnott's ventilator in the chimney will keep an ordinary paper longer clean, showing the connection of ventilation and cleanliness. Inattention to these essential matters all but foils the best nurse's best efforts.

How to clean.—Dust is the harbourer and harbingers of disease. Dust in hospitals may contain enormous numbers of living organisms.

The only way to *remove* dust is to wipe everything with a damp cloth. And all furniture ought

to be so made that it may be wiped with a damp cloth without injury to itself, and so polished or glazed that it may be damped without injury to us. Flapping, by way of dusting, is not cleaning. To 'dust,' as usually practised, merely means to distribute dust more equally over a room.

No one atom of dust ever actually leaves the room under the ordinary system of 'dusting.' The greater part of nursing consists in keeping clean. No ventilation can freshen a sick-room where the most scrupulous cleanliness is not observed.

Bed and bedding; linen, &c.—The most dangerous effluvia we know are from the excreta of the sick; these are often placed, at least for a time, where they must throw their effluvia into the underside of the bed, and the space under the bed is seldom aired; indeed, it cannot be, so long as there is a valance or counterpane down to the floor.

An adult in health exhales by the lungs and skin in the twenty-four hours three pints at least of moisture, loaded with poisonous matter. In sickness the quantity is often greatly increased—the quality is always more noxious. This goes chiefly into the bedding, because it cannot go anywhere else; and it stays there, because, except perhaps by a weekly or bi-weekly change of sheets, scarcely any other airing is attempted. A nurse will be careful to fidgetiness about airing the clean sheets from clean 'damp,' the clean nightgown from clean 'damp,' the new mattress from clean 'damp'; but airing the dirty sheets from dirty 'damp,' the dirty night-gown (which she is going to put on the patient after washing him) from dirty 'damp,' never so much as occurs to her. And a mattress is supposed to be aired by somebody else sleeping on it and saturating it with his own 'damp' before the patient comes to exhale into it the patient's 'damp.'

Where a patient has to lie on a mackintosh it is often desirable to place two or three layers of folded blanket under the draw-sheet, in order to secure some ventilation.

The best bed and bedding are: A metal bedstead with rheocline springs, or the woven wire-mattress, no valance and no curtains; one thin hair-mattress, light Witney blankets, no heavy cotton counterpane, which retains perspiration. Beds and bedding are best disinfected with superheated steam.

The patient should, if possible, be able to see out of the window from the bed.

Two beds, one for the day and one for the night, are desirable for the best nursing of the patient. A true nurse always knows how to make a bed, and always makes it herself. Bad bed-making has much to do with bed-sores. She hangs up the whole of the bedding to air for a few hours whenever possible. She makes the changes of linen and bed-linen—sheets and draw-sheets—as often as is necessary, which is a great deal oftener than is usually done. In hospitals, she sees to no patient using his neighbour's towel; and to different towels being used for different purposes. In private houses cases of purulent ophthalmia, ending in blindness, have been known to occur from the use of a soiled towel by another member of the family. She sees to all dirty linen, and especially bandages, being instantly removed and disinfected. In dressing wounds, removing drainage-tubes, catheters, &c., great care should be taken that no drop of discharge or of sputum should fall on the linen or bedding, and if such an accident should occur it should never be allowed to dry, but be at once wiped off with a

piece of cotton-wool wet with perchloride of mercury (1 : 500). Dirty linen should be removed immediately from the sick-room and sent to the laundry at least every day. If we are careful to take away and empty bed-pans directly, surely this is still more important with soiled sheets. In infectious cases linen removed from the bed or the patient should be placed at the bedside with as little disturbance as possible in a wet sheet, and so carried away. When bedding in bulk has to be carried through a ward or through a house before disinfection, it may be rolled in a damp sheet. The nurse who has been in attendance on an infectious case should, on going out, take a prolonged hot bath, wash her hair, and put on a complete change of clothing, which should include fresh boots. In a hospital the laundry should be in a separate building.

Bandages with any discharge on them are always to be burnt at once.

Utensils.—All chamber-utensils and bed-pans should be of white glazed earthenware with well-fitting lids. None should ever be left under the bed, but be brought to the room, and, when used, carried immediately to the closet-sink, emptied, and rinsed there. No zinc pail or pail without a lid should be carried through a ward or sick-room. The pail should be of glazed earthenware or enamelled iron, with a lid. But better no pail at all in a sick-room. Without care for these things, the doctor will tell us, 'it is impossible to nurse.' Excreta have often to be put by for medical inspection; the nurse must see to this being done properly and inoffensively, in a closed vessel—never in the patient's room or ward. As for urine, if it has to be measured and tested, there are glass-measures with covers fit for the purpose. Bed-pans should have in them carbolic-acid lotion (1 in 20). All bed-pans should have lids. Glass urinals, with wide necks, washed with warm water and soda, are the only really clean ones; zinc and white earthenware, with long necks, are never clean. After being used they should be put by the bedside, not under, and taken away and emptied at once. Small white chamber-utensils are useful, and district nurses may find old jam-pots the cleanest thing for urinals. It should be a rule, invariable—rather more important in the private house than elsewhere—that the utensil should be carried directly to the water-closet, emptied there, rinsed there, and not brought back till it is wanted.

There should always be water and a tap in every water-closet for rinsing.

Towels in a hospital should be kept separate for three separate uses, changed for clean ones as often as possible, and marked 'Hands,' 'Bed-pans,' and 'Basins.'

A solution of mercuric chloride (1 : 1,000) and some glycerine should always be by, to wash the hands.

Slop-sinks may be sluiced down with carbolic acid. *Water-closet pans* should be scrubbed with strong nitric acid, if they have been allowed to get at all offensive. Urinals, if allowed to become furred, must be sluiced out with boiling water, and then, if necessary, scraped with a knife all round and inside the grating; so also water-closet slop-sinks. These all should be scrubbed with sand and chlorinated lime at least twice a week. In hospitals the head-nurse ought to mop-out and rinse-down the urinals every morning herself with a little bed-

pan mop, and let boiling water run through; the same with the water-closet pans. The lavatory basins, when used, should be mopped-out and scrubbed with sand every morning. There should be two mops—one new one for lavatory basins, appropriated when a little old to the bed-pans, and the old one replaced with new; the new mop to hang over the lavatory basins, the old one to hang over the slop-sink for bed-pans; an old bottle-brush for the handles of bed-pans, a new bottle-brush, kept in the ward-kitchen, for bottles. Ordinary basins should be washed with tow, which can be burnt after use.

3. Personal Cleanliness, Precautions against Finger-poisoning, &c.—One of the most important points nurses have to be taught on beginning surgical ward-work (and, indeed, surgeons also), is how not to poison their fingers. No good nurse will poison her own fingers any more than her patient's.

The following rules should be strictly observed, noting only that many efficient disinfectants are now in use:—

Anything which has soiled the fingers or wounded the cuticle—a hang-nail, a crack, a pin-puncture—or even the condition known as ‘chapped hands,’ is a possible source of infection to others or to yourself, almost more than an open wound or sore which necessarily exacts attention. Such abrasions must be rendered harmless by thorough washing with water, dusting with iodoform, and protecting with a collodion-film. A rubber finger-stall, which can be disinfected by boiling, should be worn. Immediately *before* beginning any dressing or touching a patient, whether in dressing wounds, rubbing in applications, administering enemata, internal syringing, washing out eyes, ears, nose and mouth, turn up the sleeves, scrub the hands, wrists, and nails thoroughly with hot soda-water and soap, and soak them in some reliable disinfectant such as biniodide or perchloride of mercury, 1 in 1,000; lysol, 1 in 100; carbolic acid, 1 in 20, &c. Carbolic acid of a strength sufficient for effective disinfection causes some skins to crack, and in this way becomes a source of danger. Forceps, scissors, and other instruments, both of metal and glass, should be boiled in water containing 1 per cent. of soda (roughly a teaspoonful to the pint) immediately before use on each case, and after use should, if possible, be taken to pieces, well brushed, with special attention to serrated surfaces and joints, with hot soda-water and soap, and carefully dried before putting together again. Soiled dressings should be removed with dressing-forceps and not with the fingers; the fingers should never touch pus if contact can be avoided: on no account should adhesive plaster or other adhering dressing be scratched up with the nails. The fear of dirt is the beginning of good nursing. With all internal cases, keep the nails short, fill all crevices with soap, and carefully anoint up to their roots the fingers you are about to use, especially the first and second fingers in attending on vaginal cases, with carbolic oil or carbolic vaseline, 1 in 20. Dip the tube or nozzle to be used for any internal application in carbolic oil and, before introducing it, sponge the surrounding parts (such as the urethral orifice in introducing the catheter) with perchloride-of-mercury solution or other disinfectant. It is better to use two basins in washing wounds, so as not to dip the fingers in solution that may become soiled. Metal

and glass catheters must be cleansed and disinfected by running a stream of hot water through them, and then boiling them in soda-solution. Glass nozzles and catheters should be kept after thus cleansing in a covered jar filled with perchloride of mercury, 1 in 1,000. Catheters and nozzles of other material which will not stand boiling must be cleansed first in cold water by pouring a stream through them and briskly agitating them from side to side to clear the eye, and then in some disinfectant, carbolic acid, 1 in 20, or biniodide of mercury, 1 in 1,000, but they must not be *left to soak* in the disinfectant, as the solutions injure varnish and gum. Do not syringe down towards the eye of a catheter, but if at all in the reverse direction. Never fail to take your own carbolic soap, with which you will be provided, in your own soap-tin, into the ward each morning and evening in your pocket. But take it out before beginning ‘dressings,’ as otherwise you put a dirty hand into your pocket. Always dry your cleansed fingers and hands on towels *not* used for any other purpose. Cuffs and sleeves and stuff dresses are possible carriers of contagious matter. Always change the apron and over-sleeves which you have worn about the sick before eating or drinking. Report immediately any scratch or hang-nail or sore you may have to the ward-sister. Never go on duty in the morning without having taken a meal.

4. Food and Drink (Diet).—The physician will tell us that, to give food and stimulants in the way, at the time, of the kind, with the cooking and preparing, that will best enable the poor enfeebled digestion to assimilate it, is one of the great nursing arts. No chemical rules can be given for this as absolute. The patient's stomach is the laboratory, and also the chemist. It is the sole judge of whether the physician's orders are right, and the nurse has to watch and tell him what the patient's stomach says. She must, of course, be trained and cultivated to understand what it says.

The patient's stomach sometimes craves, and assimilates too, what no rules would have prescribed for it. The nurse must ask the physician whether she may gratify these cravings. Sick-cookery should do half the digestion's work; and proper variety is essential. Indeed, how much of the suffering of illness, as well as of its danger, is the fault not of the illness but of the nursing, is well known to the skilful physician and surgeon.

The nurse, of course, has nothing to do with the prescribing of stimulants any more than of medicines. But life often depends—especially in fevers and severe surgical injuries—upon the nurse knowing how to follow the indications of the changes to be looked for in the patient's state given her by the physician, and to change the times of giving the stimulants accordingly.

The nurse must know how to make gruel, arrow-root puddings, egg-flip, drinks, good beef-tea, and other kinds of sick-cookery, so as to please the patients' taste and vary their diet. People say ‘fanciful patients’ must be ‘humoured.’ So they must; but it is in order to excite the proper secretions of saliva and gastric juice necessary for digestion. Nothing should ever be cooked in the ward or in the patient's room.

But though ‘sweet Jack Falstaff’ says ‘A nurse is a cook,’ the whole of the cooking must not be thrown on the nurse, if she is to nurse; and above all, if she is to eat, she must not be expected to

cook for herself. But she will always be required not only to see that the patient's food and drink be as prescribed, but that it be well cooked, and punctually and well served. The physician considers that upon the nurse's power to give weak patients food in the way they like often depends their taking, or at least assimilating, any food at all.

She has also to feed, for example, fever-cases so that they can eat. The mere lifting-up of a patient in bed to give him food may terminate fatally a fever-case. The nourishment or stimulant ordered may have to be put into his mouth perhaps every half-hour—perhaps every few minutes—without rousing the patient. The physician expects the nurse to be able intelligently to make the variations he prescribes in giving these things, especially during the night, according to the state of pulse and other symptoms, which she must know how to observe, in order to follow his conditional directions, upon which hangs the patient's life from hour to hour, often from minute to minute. In convalescence from typhoid fever, one single false indulgence has often induced a fatal termination.

5. Application of Remedies.—The physician or surgeon requires the nurse—

To be able to dress blisters, burns, sores and wounds.

To administer stimulants and medicines as ordered, enemata and injections to men and women, and suppositories.

To manage trusses, appliances in uterine complaints; to pass the catheter—at least for women. The district nurse is often now required to pass the speculum for women, also the catheter for men, because there is no one else to do it.

To use the best methods of friction to the body and extremities; to make and apply fomentations, poultices and minor dressings, wet and dry or greasy; to syringe wounds; to syringe the vagina.

To manage helpless patients—fever, operation and surgical cases—that is to move, to change their linen, to keep them personally clean, warm or cool.

The medical attendant will expect the nurse to maintain an exquisite cleanliness of the patient's whole person and skin, and, in fever—the daughter of dirt—to clean the patient's teeth, gums and tongue, with lemon-juice or white-of-egg beaten to a froth. A nurse is no nurse who cannot wash or sponge a patient's whole body *without exposure or chill to any part*. In typhoid and other fevers, this is often an essential part of the treatment.

To give food and stimulants to helpless patients—fever, operation and surgical cases; to manage the position of such cases; to prevent or to dress bed-sores.

To make the sick-bed, and especially to make the bed with the patient in it; to change the under-sheet without moving the patient, as in fever and operation cases. The 'best way' includes, in this as in all other things, the doing them at the least expense to the patient's vital powers.

To prepare the bed for accidents and various kinds of operations; to undress, handle and put to bed accident cases.

To attend at and prepare for operations: to prepare patients for and manage them after operations and anæsthetics—and all this with the least call upon their small strength.

To be able to do the first thing in case of hæmorrhage, namely, compression by hand or finger, by extemporary tourniquet and plugging.

To bandage all the various parts of the body, arm, leg and chest (in Paris the *infirmiers* of military hospitals are made to practise all this, till not only it is done perfectly, but in a given number of minutes).

To make bandages of various kinds: T-bandages, double-headed, 'binders,' many tailed, ovariectomy, triangular, starched, and plaster-of-Paris, and other stiff bandages.

To make rollers, to line and pad splints, to make leather and gutta-percha splints, fracture- and chaff-pillows, and sand-bags.

The nurse should be able to give subcutaneous injections, to use the galvanic battery, to dry- and wet-cup, and to apply leeches externally and internally.

She is required to be able to apply dry and moist heat; to give inhalations and use the spray-disperser; to apply cold, with the use of syphons and with ice; and to carry out aseptic or antiseptic treatment. Every surgeon and physician has his own 'antiseptic solutions,' his own 'disinfectants,' and every year brings fresh ones. And what is ordered must of course be used by the nurse.

6. Observation of Patients.—The physician and surgeon require every nurse to be able to observe correctly, and to report correctly, on the state or character of secretions, expectoration, pulse, skin, appetite, strength; effect of diet, of stimulants and of medicines; eruptions; the development of swellings or other abnormalities; the characters and starting-points of fits; as to intelligence, with regard to delirium, stupor, &c.; as to breathing, whether quick or slow, regular or irregular, difficult, &c.; as to sleep, whether sound, starting, heavy, &c.; and as to the state of wounds. The physician also requires the nurse to be able to 'take' and to record the temperature—sometimes every quarter of an hour in critical cases—the pulse, the respiration; to measure, and sometimes to test the urine for him. She will be required to make these observations—if possible still more accurately—for child-patients, who cannot tell what is the matter with them; to understand the management of sick children and children's wards, which need a yet more exquisite cleanliness. And children show a much more rapid change of symptoms for life or for death generally than adults. Children are the best air-test, the best test of sanitary conditions.

Other Duties.—She must understand the management of convalescents—a whole department of nursing in itself—and the sooner a convalescent, especially a convalescent child, is removed from hospital to a country 'home' the better.

Housekeeping.—She must understand a certain amount of housekeeping or domestic economy—rather an uncommon talent. She must be able to order the proper quantity of bread, milk, butter, &c., and to prevent waste.

She must be competent to undertake the charge of linen—a most important item of nursing.

Generally.—Nursing is, above all, a progressive calling. Year by year nurses have to learn new and improved methods, as medicine and surgery and hygiene improve. Year by year nurses are called upon to do more and better than they have done. It is felt to be impossible to have a public register of nurses that is not a delusion.

Further, year by year, nursing needs to be more and more of a moral calling.

Night-nursing.—The physician or surgeon requires the night-nurse to be as good as, or even better than, the day-nurse, for the most critical times of fever and severe surgical injury often occur at night, or in the very early morning. But quite the same kind of business capacity is not required in the night-nurse as in the nurse in day charge of wards. Night-nurses, to do their work well, must have at least seven or eight hours in bed where they can sleep undisturbed by day. They must have hot meals prepared for them when they come off duty in the morning, and before they go on duty at night; besides breakfast at 1 or 2 a.m. They must have one and a half or two hours' exercise. In a hospital they should be obliged to show their pass. It is rather more necessary for a night-nurse to be regular in her habits, if she is to be well and efficient, than for a day-nurse. And there appears no reason why nursing by night, if properly managed, should be more trying than by day. But regularity of habits, of meals, of sleep, of exercise, of personal cleanliness, is the *sine quâ non*. Occasional breaks or transfers to day-duty may be necessary; or a night or two in bed every month for a night-superintendent. But a too frequent shifting (e.g. every month or every three months) from day to night duty seems hardly advisable, for it takes some time for a nurse to accustom herself to sleep by day. A night-nurse may deteriorate in two ways, if not carefully supervised: (1) She may become 'bumptious,' and too independent. (2) On the other hand, she may become careless and hard from having too much to do to do it properly. The night-nursing in the medical wards of a large hospital is generally much 'heavier' than in the surgical wards, and the matron ought to know from her own experience when the night-nurse absolutely requires additional help, and to provide it. Instant help should also be within call in an emergency, such as a patient becoming suddenly delirious. And the night-superintendent should always be on the watch for emergencies.

Holidays.—All nurses, especially night-nurses, must have holidays, as well as occasional recreation. A month's regular holiday in the year is not too much. Yet more do matrons and superintendents and all women filling nursing offices of great responsibility require an annual holiday, if they are to maintain vigour of body and mind, and not to wear out prematurely.

What a Nurse is to be.—A really good nurse must needs be of the highest class of character. It need hardly be said that she must be—(1) Chaste, in the sense of the Sermon on the Mount; a good nurse should be the Sermon on the Mount in herself. It should naturally seem impossible to the most unchaste to utter even an immodest jest in her presence. Remember this great and dangerous peculiarity of nursing, and especially of hospital nursing, namely, that it is the only case, queens not excepted, where a woman is really in charge of men. And a really good trained ward 'sister' can keep order in a men's ward better than a military ward-master or sergeant. (2) Sober, in spirit as well as in drink, and temperate in all things. (3) Honest, not accepting the most trifling fee or bribe from patients or friends. (4) Truthful—and to be able to tell the truth demands attention and observation, to observe truly—memory, to remember truly—power of expression, to tell truly

what one has observed truly—as well as intention to speak the truth, the whole truth, and nothing but the truth. (5) Trustworthy, to carry out directions intelligently and perfectly, unseen as well as seen, 'to the Lord' as well as unto men—no mere eye-service. (6) Punctual to a second, and orderly to a hair—having everything ready and in order before she begins her dressings or her work about the patient; nothing forgotten. (7) Quiet, yet quick; quick without hurry; gentle without slowness; discreet without self-importance; no gossip. (8) Cheerful, hopeful, not allowing herself to be discouraged by unfavourable symptoms; not given to depress the patient by anticipations of an unfavourable result. (9) Cleanly to the point of exquisiteness, both for the patient's sake and her own; neat and ready. (10) Thinking of her patient and not of herself; 'tender over his occasions' or wants, cheerful and kindly, patient, ingenious and *feet*. The best definition can be found, as always, in Shakespeare, where he says that to be 'nurse-like' is to be

'So kind, so duteous, diligent,
So tender over his occasions, true,
So feat.'

A patient wants according to his wants, and not according to any nurse's theory of his wants or 'occasions.' 'Tender over his occasions' she must be; but she must have a rule of thought; and this the physician or surgeon has to give her in his directions; which her training must have fitted her to obey intelligently, using discretion. The nurse must have simplicity and a single eye to the patient's good. She must make no demand upon the patient for reciprocation, for acknowledgment or even perception of her services; since the best service a nurse can give *is* that the patient shall scarcely be aware of any—shall perceive her presence only by perceiving that he has *no* wants. The nurse must always be kind and sympathetic, but never emotional. The patient must find a real, not forced or 'put on,' centre of calmness in his nurse. To call upon a patient by emotion for emotion is the most cruel, because useless, demand upon his strength. It is asking him to bear your troubles and your anxiety as well as his own. Suppressed emotion is as bad—it makes the nurse constrained. It is exposing the patient to both frost and fire. Half the battle of nursing is to *relieve your sick from having to think for themselves at all*—least of all for their own nursing.

NUTMEG LIVER.—See LIVER, Passive Congestion of.

NYCTALOPIA or NIGHT-BLINDNESS (*νύξ*, night; and *ὤψ*, the eye; the letters 'al' probably represent *alpha privativum*, and express *want of*).—**SYNON.**: Fr. *Nyctalopie*; Ger. *Nyctalopie*; *Nachtblindheit*.—By the term 'nyctalopia' is meant an abnormal degree of impairment of vision at night, or whenever the light is dim. The degree of impairment ranges in different cases from slight embarrassment to practical blindness. During the day or in a good light the vision may be of normal acuteness, but rapidly fails at dusk.

Like hemeralopia, the term 'nyctalopia' has been used in the opposite senses of *night-blindness* and *day-blindness* (see **HEMERALOPIA**). Many modern writers have used it in the latter significa-

tion; but all the ancients, and nearly all the later writers to the end of the seventeenth century, used it in the former. In the nomenclature of the Royal College of Physicians of London the original meaning is adopted.

Though night-blindness is at all times merely a symptom manifested in several diseases, it is convenient to classify it as *symptomatic* when associated with certain appreciable morbid changes in the fundus oculi; and *idiopathic* or *essential* when unaccompanied by such changes.

Of *symptomatic nyctalopia*, by far the most common concomitant is retinitis pigmentosa. It may occur in connection with detachment of the retina, with syphilitic and other forms of retinitis and choroiditis, and with some embryological defects or intra-uterine diseases of the retina or of the choroid. In all the affections of this group the beginning of night-blindness is insidious, and the course is chronic, the physical condition being some morbid alteration in the percipient and pigmentary layers of the retina.

Idiopathic nyctalopia is usually more or less abrupt in its onset, and due to torpor of the retina, showing itself by deficient adaptation of the retina to feeble illumination; and is an exaggeration of the physiological blindness which temporarily takes place in passing from bright into feeble light. In many instances it follows prolonged exposure of the eyes to intense glare of any kind. This is especially apt to occur in persons who have been insufficiently or improperly fed, or who show malnutrition from any cause. Formerly it was often met with as an early symptom of scurvy, and it still occurs epidemically among the poor in those countries where strict religious fasts are observed. It is also observed in some cases of anæmia, albuminuria, liver-disease with or without jaundice, pregnancy, malaria, and chronic alcoholism. In many cases of idiopathic nyctalopia there co-exists a peculiar form of xerosis of the bulbar conjunctiva. On the conjunctiva opposite the palpebral fissures are scaly oily-looking patches, which, by gentle frictions of the lids, can be whipped into a fine white foam abounding in minute bacilli. The exact relation between the xerosis and the nyctalopia has not been determined. The xerosis may only be an expression of impaired nutrition of the eyeball.

The *prognosis* of symptomatic night-blindness is generally unfavourable; while that of the idiopathic form is more favourable—at least in so far as the associated constitutional and local states may be amenable to treatment.

TREATMENT.—This must necessarily be determined by the ætiological and associated pathological conditions. Of the symptomatic form the treatment is that of the accompanying retinal or choroidal affection; and of the idiopathic form the treatment will be that of the associated constitutional and local conditions. The eyes should be protected by tinted glasses, shades, or bandages; faults and errors of diet corrected; cleanliness of the lids ensured; and tonics and other regimen and medicaments suited to the special requirements of the particular case must be employed. JOHN TWEEDY.

NYMPHOMANIA (νύμφη, the nymph, a portion of the female sexual organs; and *μανία*, madness).—A form of mental derangement in women, characterised by an insatiable desire for sexual intercourse.

NYSTAGMUS (νυσταγμός; from νυστάζω, I nod). Rhythmical, involuntary, frequent oscillations of the eyeballs, of small range and more or less continuous. The movements are not commonly horizontal, but may be vertical, rotatory, convergent, or mixed in direction. They are usually binocular, but may be unilateral, and then are said to be generally vertical; they consist usually of a rapid movement in one direction and of a slower return. The rate varies from 60–200 per minute, rarely slower, sometimes faster; the rhythm is regular; the range most commonly from 2–4 mm. (Gowers). The movements cease during sleep, are often increased by observation and by violent exertion, are most obvious during fixation of a somewhat distant object, and are sometimes suppressed on strong convergence; they may be so fine as only to be noticed on ophthalmoscopic examination. The movements of the eyeballs are otherwise unaffected, but the field of fixation is reduced. Nystagmus may be present in all positions of the eyeballs, or only in certain directions of movement, when weakness of affected muscles is often present. Slow movements become quicker when the eyes are moved (Gowers). *Associated movements* sometimes occur; oscillatory movements of the head, generally opposed in direction to the eyes, and partly compensatory; simultaneous movements of the upper eyelid or contractions of the orbicularis palpebrarum; hippus; torticollis spasm; in children clonic contractions of the neck-muscles (Bruns); in one case similar lateral movements of the pharynx and larynx (Gowers).

VARIETIES.—Nystagmus is seen in health in a person looking at a quick succession of moving objects, and also in anyone rapidly rotated on a table spinning on its vertical axis.

Experimentally it is commonly observed, at least temporarily, after electrical irritation of the cerebellum; more frequently in lesions of the cerebellum (Ferrier). Risien Russell considers that the experimental evidence points to lateral nystagmus, with jerks towards the side of lesion, as associated with lesion of a lateral lobe, and irregular or rotatory with affections of the middle lobe of the cerebellum. Nystagmus may be *congenital* or *acquired*.

I. Congenital Nystagmus.—Congenital nystagmus is present during rest and in all positions of the eyeballs; there is no apparent movement of objects, and the patient is only conscious of weakness of vision. It appears soon after birth or in early infancy. It is generally associated with eye-diseases which impair visual acuity, e.g. diseases of the retina and choroid, congenital cataract, corneal nebulae, very rarely anomalies of refraction. It occurs in albinism. Nystagmus may also be present in congenital defects of the brain, and in cerebral disease or injury in early infancy. It very constantly appears in the affection of infancy known as 'Head-Nodding,' in which it is generally bilateral, may precede the head-movements and persist after them, and sooner or later almost always disappears. *See HEAD-NODDING IN CHILDREN.*

II. Acquired Nystagmus.—In acquired nystagmus the patients may be unconscious of its presence, but many complain of 'dancing of objects' before the eyes, this apparent movement being generally in the same direction as the nystagmus. In the following varieties eye-diseases may aggravate but do not cause nystagmus.

1. Occupational.—Miner's nystagmus is the most

common, but it occurs in other occupations involving continued strain on the movements of the eyes. See OCCUPATION-DISEASES.

2. *Symptomatic*.—In disseminated sclerosis it is a common and often an early symptom. The direction varies, but it is most commonly horizontal; it is generally bilateral, and only present when the eyes are moved, but may be constant. In Friedreich's ataxia nystagmus is often present in lateral positions of the eyeballs. It is sometimes found in the chronic stage of acute maladies, such as disseminated myelitis, and in ataxic paraplegia on movement of the eyes (Gowers), and rarely in primary spastic paraplegia, syringomyelia, progressive muscular atrophy, and amaurotic family idiocy. In tumours of the cerebellum it is frequent (24 out of 41 cases, Ferrier), much less so in cerebellar abscess, and absent in cerebellar atrophy. It occurs in cerebral tumours, hæmorrhages, and softening in various situations, according to some authors especially in lesions of the optic thalamus and fourth ventricle; in thrombosis of sinuses, chronic hydrocephalus, pachymeningitis hæmorrhagica, sudden general anæmia of brain, and temporarily after severe concussion. It is rare in tubercular, but more common in posterior basic meningitis. In Cheyne-Stokes' respiration it may accompany the period of activity. It may occur in eclampsia nutans, and rarely as a sequel of epileptic attacks.

3. *Aural*.—Nystagmus may occur in severe attacks of aural vertigo, and in diseases of the ear attended by increase of pressure within it.

4. *Toxic*.—In uræmic convulsions it is occasionally present, and this fact may be connected with its appearance in rabbits after the injection of hypertoxic urine into their veins. It occurs in benzene-poisoning together with immobility of pupils, and in chronic alcoholism as the result of cerebro-spinal sclerosis (Bevan Lewis).

5. *Reflex*.—Nystagmus is said to occur temporarily from some peripheral irritation; carious teeth (Ross); injury to opposite eye.

6. *Voluntary*.—A case is recorded in which rapid lateral nystagmus could be produced voluntarily and maintained for a minute.

DIAGNOSIS. — True nystagmus must be distinguished from slight nystagmoid jerkings, especially in lateral positions of the eyeballs, met with in parietic conditions of the ocular muscles, in debilitated states, and in some hysterical cases; in the last it is often associated with characteristic blinking of the eyelids (Russell). According to the best authorities nystagmus does not occur in hysteria. As the varieties of nystagmus which are found apart from diseases of the nervous system can be excluded by the history and conditions present, nystagmus is valuable in diagnosis chiefly because it points to organic disease of the nervous system, and is sometimes an early symptom of it; in doubtful

cases of nervous disease its presence in different directions of movement of the eyes should be carefully sought for. The association of nystagmus with pallor of the optic discs is important in the early diagnosis of some cases of disseminated sclerosis. As a localising symptom of intracranial disease, it is not available, but the facts given above as regards the cerebellum should be remembered.

MODE OF PRODUCTION.—The causes of nystagmus are thus very numerous, as would be expected in view of the wide connections of the centres for the ocular movements. In all cases the seat of disturbance must be referred to these centres, and not simply to fatigue of the ocular muscles themselves. The power of steady, sustained fixation of the eyes in binocular vision is not present at birth, but during the first few weeks or months of life the neuro-muscular mechanisms of the eyeballs are educated to act in co-ordination with the visual perceptive centres. A reflex action of great delicacy is thus formed, by which in fixation the image of the object falls upon the macula. But this reflex co-ordination of ocular muscles and perceptive centres cannot be established if in early infancy there is defect of vision, especially one which lowers the visual acuity of the yellow-spot region. While the congenital form is thus explained, in the other varieties in which there is no ocular disease the conditions present probably interfere with the action of the oculo-motor centres, either directly or through the tracts which reach them from other parts of the brain. Thus in the nystagmus in rapid rotation of the body, and in certain ear-diseases, the centres are disturbed through their connection with the semicircular canals. It is difficult to explain why under such circumstances the steady contraction of the muscles during fixation in health should be changed into the oscillations of nystagmus. When any movement is carried out the opponents of the muscles concerned also contract, and so the resulting action is rendered steady; if from any cause the centres for the ocular movements did not act exactly synchronously on the two sides, an alternating contraction of the muscles might result. The intermittent character of nystagmus is explained by Gowers on the supposition that the centres have a tendency to rhythmical, intermittent action which is normally kept in check, and when this is removed, intermittent spasm of the ocular muscles results. See NERVOUS SYSTEM, Physical Examination of.

TREATMENT. — Treatment of the occupational form consists in a change of work; resumption of the old employment results sooner or later in a relapse. Tonics, especially strychnine, and sometimes bromides, are useful. In the congenital form an effort may be made to correct any marked strabismus or errors of refraction.

J. MICHELL CLARKE.

O

OBESITY (*obesus*, corpulent; from *ob*, by reason of, and *edo*, I eat).—**SYNON.**: Corpulence; *Poly-sarcia*; Fr. *Obésité*; Ger. *Fettsucht*; *Fettleibigkeit*.

DEFINITION.—This term is applied to a general state of disordered nutrition of the body, characterised by an excessive development of adipose tissue and various disturbances in the bodily functions.

ÆTIOLOGY.—(a) **Predisposing Causes.**—The influence of *heredity* in transmitting the liability to obesity is undoubted, and is a matter of common knowledge. But an examination of the families of fat people appears to show that obesity is indifferently transmitted with rheumatism, gout, oxaluria, diabetes mellitus, and gall-stones; all which perversions of nutrition are in some manner closely correlated. *Sex and Age.*—That excessive corpulence is more common among women than among men is also well known. Several circumstances have been suggested to account for this, such as the menstrual functions of women, pregnancy and suckling—from which fitness often dates, their less muscular activity as compared with men, and their frequently diminished oxidative power, due to poverty of red blood-corpuscles. Age appears to have considerable influence in determining this condition. Under a healthy regimen children get fat from birth, notwithstanding that at the same time the proteid ingesta must be largely employed in the construction of the rapidly growing tissues; and hence, at this period of life, the fat and starchy food-stuffs are the chief sources of the adipose deposit. Children frequently are seen, improperly fed on excess of starchy matter, yet very fat, while their general nutrition is much impaired. At puberty there is frequently a diminution in weight, both relatively to the height and absolutely; but the contrary to this sometimes accompanies the establishment of menstruation, especially if the subject be very chlorotic—that is, with an enfeebled oxygen-carrying blood-power. After the age of forty, particularly in women at the climacteric, the influence of age markedly asserts itself. Even the manifestation of the hereditary tendency may be postponed until that period, and for women to become fat at that time is very common. The perversion of nutrition now under consideration is, in some unknown way, curiously but distinctly associated with the degree of development of the sexual functions, and in an inverse direction. This is very noticeable in eunuchs and animals whose generative organs have been removed, and the part played by the cessation of ovulation has been already mentioned. Even during pregnancy, when ovulation is suspended, it is no uncommon occurrence for the subcutaneous fat to be increased in amount. *Occupations.*—Those compelling a sedentary life undoubtedly favour the development of corpulence, especially if there be hereditary predisposition, together with large eating and alcoholic indulgence. *Race.*—Among certain races obesity appears to prevail, as for instance the Hottentots; and while among some, such as certain castes of Hindoos, the condition has been highly esteemed, among others, as the Greeks and Romans, it was regarded as dis-

graceful. *Climate.*—Although very fat people are met with in all climates, there appears to be a special tendency to their predominance in low-lying, damp countries, while, with certain exceptions, they are less often seen in very hot and in mountainous districts.

(b) **Determining Causes.**—Excess of *food* is the first of these to be mentioned. While no doubt a large excess of food may lead to corpulency, it must be confessed that it very often does not do so, and extremely thin persons are often large eaters. And, on the contrary, many women who become excessively obese have poor appetites. It has been estimated by Bouchard that 40 per cent. of the obese are large eaters, and that 10 per cent. eat less than the normal quantity. Nor does it seem in these different classes of cases that the kind of food makes much difference. Some get fat, eat what they will; others do not, whatever their diet. Nevertheless, starches and sugars are, as a rule, more effective fat-producers than fats. *Drink.*—It is, however, usually the case that very fat people take a large amount of fluid food. How alcohol acts in the production of fat is not very clear. It is asserted that it does so by diminishing oxidation; but this is not the entire explanation, for the extent of obesity is far from being proportionate to the amount taken, and not infrequently an excessive ingestion is not associated with corpulency. There would also seem to be something due to the form in which the alcohol is taken. *Exercise.*—Deficient muscular activity, by diminishing the amount of oxidation of tissue, favours obesity, especially in cases of idleness following on a period of considerable energy, the quantity of food taken remaining the same; and since, as a rule, the stouter the person, the less capable is he of exercise, these two conditions react one upon the other, in favour of fat-production. But lack of exercise, like over-feeding, is not invariably followed by corpulence, nor are the two conditions when combined. Bouchard indeed calculates that only 37 per cent. of fat people take too little exercise, and 28 per cent. even exceed the average man in this respect. *Disease.*—Exceptional cases of corpulence have followed recovery from severe fevers, and extensive bleedings, even when there had been no predisposition; and a similar result has been met with after prolonged administration of mercurials and arsenic, which is perhaps to be explained by the deteriorating influence that these drugs are said to possess on the red blood-corpuscles.

PATHOLOGY.—Assuming that the current views on lipogenesis, or fat-formation, are known to the reader, it is sufficient here to state that from whatever source the fat of the body be derived, whether from the fatty, the starchy, or proteid elements of the food, or from all, as is most probable, the fact of its being stored up as adipose tissue must be regarded chemically as an expression of deficient or delayed oxidation—a process which, if it had been more complete, would have resulted in the conversion of these elements into carbonic acid and water, to which the fat itself is reduced when it is subsequently used up in the economy. It is thus that the corpulence that frequently attends such

morbid states as anæmia, chlorosis, hæmorrhage, some pulmonary and cardiac diseases, and alcoholism, is to be explained; since in all these diseases the oxygenating power of the blood is deficient.

The fat of the body in an average male adult constitutes about one-twentieth, and in the female rather more, of the total weight. It is not for $3\frac{1}{2}$ months after the commencement of development that the adipose tissue is sufficiently differentiated to be distinguishable; it gradually increases in amount, being considerable at birth and up to puberty, when it often diminishes slightly; during maturity it increases, or the reverse, being very variable in amount; and during old age it decreases. During childhood the adipose tissue is more evenly distributed in the subcutaneous tissue than in later life, when fat tends relatively to diminish on the surface in proportion as it becomes deeper-seated.

In the three situations in which the fat is chiefly deposited—namely, the subcutaneous, subserous, and intermuscular connective tissue—there are certain areas which are preferred by it, as there are others which escape. While the abdomen, buttocks, breasts and neck are especially prominent, the wrists, ankles, eyelids, scrotum, and penis are free from fat. Beneath serous membranes it is very unequally distributed. Fat is never seen beneath the peritoneal coat of the stomach or intestines, the parietal pericardium, or the visceral pleura; while the great omentum, which usually weighs about $\frac{2}{3}$ lb., may reach to 7 or 8 lbs., or, it is said, even 30 lbs., and a thickness of half an inch or more of fat may be included between the layers of the mesentery. A considerable amount is developed beneath the visceral pericardium; and under the synovial membranes fat may be deposited to such an extent as to interfere with the movements of the joints. Adipose tissue is never found within the cranial cavity, but may be present in large quantity in the spinal canal.

The ordinary state of the organs found in very corpulent people is, that the lungs are small; the heart and the liver large, and infiltrated with fat, the cavities of the former being dilated, with degeneration of the muscular fibres; and the latter showing a state of partial cirrhosis or being extremely fatty; the gall-bladder containing only a little pale bile or mucus; the stomach large and muscular, but well-developed, and the intestines often dilated; the kidneys small, as also the spleen and lymphatic glands; and the pancreas largely developed. In extreme cases the blood may contain four to five times the normal amount of fat, sufficient to give it an altered appearance to the naked eye.

Like many other conditions of disease, it is impossible to define the exact line at which a morbid obesity may be said to commence. All degrees of corpulence, indicated by such terms as 'stout,' *embonpoint*, &c., occur, to which the notion of disease is wholly inapplicable. Nor can disturbance of function be taken in all cases as the measure of a morbid state, since the impairment of function is not always proportionate to the amount of fat.

In extreme cases one-half, or three-fourths even, of the body-weight may be fat.

SYMPTOMS.—The general appearance of a corpulent person scarcely needs description. The condition may be associated either with a hyperæmic or full-blooded, or with an anæmic state of

body (the hæmoglobin being deficient in amount rather than the corpuscles too few), and it is desirable to recognise this in view of treatment. Owing to the fatty infiltration of the muscular tissues, and the degeneration of the fibres, the muscular energy is diminished, this being especially noticeable in regard to the heart, the action of which is easily disturbed, so that palpitation is a frequent symptom, accompanied by dyspnœa, induced by slight exertion. The affection of the voluntary muscles manifests itself in an indisposition to active exercise. The digestive power is often very well maintained, and this notwithstanding the frequent excess both in the quantity and in the quality of food indulged in. Periodical impairments are, however, frequent; and pyrosis, flatulence, and constipation or diarrhœa, with offensive stools containing much fat, are often troublesome. The cardiac sounds are usually feeble and distant, though the reverse obtains when there is a hypertrophied ventricle. The pulse is very variable, full, or small and weak, according to the plethoric or feeble state of the individual; more or less frequent than normal, irregular or dicrotic, dependent on the degree of fatty change in the heart, or, if of high tension, from fibrosis of the arterioles (*see* HEART, Fatty Accumulation on). The mental activity is uncertain, and many external causes tend to modify it; but the temperament is proverbially 'easy-going,' indolent, and lethargic, especially after meals, although very frequently interrupted by attacks of peevishness and irritability, or by unusual somnolence and quiet. The remarkable condition known as 'narcolepsy,' which is characterised by sudden brief attacks of irresistible sleep, is sometimes observed in the obese, both with and without such complications as albuminuria and diabetes. Examples, however, of considerable intellectual attainments are not unknown among the corpulent. Profuse sweating is induced by slight exertion, and the secretion of the sebaceous glands is abundant and often fetid. The urine is generally acid, often diminished in quantity, and contains an excess of uric acid, urates, and frequently oxalate of calcium. Partly from chafing, and partly from the excessive cutaneous secretions, intertrigo and other eruptions are apt to occur in the folds of the groin, below the mammae, and in similar parts. The vessels share in the general malnutrition of the tissues, and atheroma of the arteries is often found, while the veins become distended and varicose, forming hæmorrhoids and varicocele. Some œdema of the ankles is also usual, and hæmorrhages from nose or lungs are not uncommon. Depending upon these vascular changes are the congested and bloated appearance of the face, and the liability to headaches, vertigo, and giddiness. Disturbances of sight and hearing are frequently noticed in fat people. Irregularities of menstruation, which may be early in appearance, are frequent. The sexual appetite is frequently deficient in both sexes, and sterility is common in women: in man it has been attributed to the deposition of fat along the course of the spermatic vessels, causing impaired nutrition of the testes, as shown by the scanty and inactive spermatozoa found in the semen. Accumulation of fat around the umbilical ring favours the occurrence of hernia in this situation, a not uncommon event in the corpulent. The enormous weight of the abdomen causes a constant backache from painful overstrain of the dorsal muscles.

The condition of obesity, like other general perversions of nutrition, most distinctly presents other characteristics than the mere signs and symptoms above enumerated. 'Corpulence is not only a disease itself, but the harbinger of others,' as Hippocrates pointed out. There are certain tendencies and liabilities which the state engenders; and intercurrent maladies come to possess special features. Periodically, the fat man ails without perhaps any obvious cause, and such ailments must be regarded as the expression of malnutrition of the tissues produced by the excess of fat. Among the more prominent of these affections is a proneness to catarrh of the respiratory and alimentary mucous membranes, and periodical 'colds' and diarrhoeas are frequent. This is in great part due to the fact that the power of self-regulation of temperature, which the body possesses, is diminished by the thick layer of subcutaneous fat, which is a bad conductor of heat, and interferes with compensatory radiation. At the same time the plethoric condition, and the enfeebled circulation due to the weak heart, tend to the same end, namely, a liability to congestion of the ill-supported tissues, such as the mucous membranes, with the results of such congestion in excessive secretion and other derangements of function.

The obese subject is quite as liable to the acute diseases as is the thin man; and these maladies run in him a singularly unfavourable course. The diminished power of heat-radiation increases the pyrexia; and the weak heart favours the establishment of the adynamic state. Such means for lowering the temperature as cold applications have but little effect through the thick fat; and aconite is contra-indicated by the pulse. But since the oxidising process in the corpulent is diminished, the temperature in the febrile state is rarely very high, and at the same time is but ill resisted.

The effective agent in fat-formation, namely, deficient oxidation, also favours the formation of uric acid, and hence the fat are often gouty. Saccharine urine (a condition which, whatever view be taken of its pathology, is manifestly an expression of deficient oxidation)—especially that form which is met with in those advanced in life—very frequently occurs in stout people, not only in an intermittent form, but constantly with other symptoms of true diabetes mellitus. In 32 of 140 cases of diabetes mellitus observed by Seegen, obesity preceded the glycosuria.

A somewhat infrequent form of obesity, occurring chiefly in middle-aged women, has received the name of *adiposis dolorosa* (p. 28). It is characterised by local fatty swellings, sometimes symmetrical and usually in the arms, in addition to a general state of obesity. Severe paroxysmal pain is associated with the swellings, which are often very tender, with a general anæsthesia of the surface elsewhere. Such patients tend to exhibit periods of dementia, or epileptical attacks. Headache, cutaneous pigmentation and a liability to hæmorrhage have been observed. A previous history of alcoholism or of syphilis has been generally obtained. Portions of nerves removed from the painful areas have shown the changes characteristic of neuritis.

PROGRESS AND PROGNOSIS.—The progress of obesity is essentially chronic. Extreme fatness in the very young, however, usually subsides; but the obesity of advanced life never does, unless any exhaustive disease should co-exist, such as cancer

or diabetes; and the latter by no means produces then the emaciation that it causes in young people. Obesity should, on the whole, be regarded as a grave matter, since very fat people rarely reach an advanced age; while a decrease of fat at middle age in a person hitherto stout should be regarded with suspicion.

In obesity, death by syncope may result from an extremely fatty heart; from apoplexy, caused by rupture of an atheromatous vessel in the brain; or from acute pulmonary congestion, with general œdema from cardiac dilatation; while rupture of the heart, angina pectoris, and uræmia are among the dangers to which the obese are liable. Not infrequently some sudden exertion has immediately preceded the fatal end.

TREATMENT.—Recognising that accumulation of fat is a perversion of nutrition, which, if once established, and with a strong hereditary predisposition, cannot be cured, it follows that we should endeavour to prevent as far as possible its increase, by avoidance of those factors which pathology tells us are favourable to its development. The guides as to how far a given plan may be proceeded with are, first of all, the age and general condition of the patient, especially as regards the heart's power; and, secondly, the feelings and capability of the patient, as the treatment is pursued. Each case must be treated according to circumstances, bearing in mind that the objects to be aimed at are to diminish the sources of the fat, and to increase the oxygen-carrying power of the blood and oxidising power of the tissues. Unless the patient actually suffers from the accumulation of fat, it is generally undesirable to pursue any special treatment, and under no circumstances should the weekly loss be allowed to exceed 3 lbs., and the total loss should not go beyond 28 lbs. It must be remembered that some persons far from deriving benefit from any regular plan of treatment distinctly deteriorate in health, and caution should be exercised in the selection of cases.

The diet must be regulated in quantity and quality. Since a healthy diet should consist of certain proportions of nitrogenous, carbohydrate, and fatty principles, and since from all these three substances fat may be formed in the body, the question arises, which can be most advantageously diminished. Experience supports our pathological knowledge in advocating a withdrawal as far as possible of fatty and more especially starchy food, while at the same time a moderate increase in proteid matter is permitted; for with a fair quantity of the other food-stuffs, proteids increase tissue-change. It is on this principle that systems of dietary for the corpulent are founded, the best known of which bears the name of Banting, who in a year (1863) reduced his weight by 44 lbs., and without any recurrence of corpulence when ordinary diet was resumed. There are many other cases recorded. Dr. Cheyne, who weighed 32 stone, reduced himself a third in weight, and lived afterwards in good health to the age of seventy-two. Lean meats, sweetbread, fish—except rich kinds, such as salmon and eels—clear soups, poultry, game, eggs, cheese, green vegetables, toast, gluten-bread, fresh fruit, and pickles are allowable articles of diet. An average diet for an adult would be 12 oz. lean meat, 6 oz. rusks or gluten-bread, 4 oz. green vegetables, 1 oz. butter, and 1½ pint tea. If the normal daily requirements be put at—

proteids 130 grammes, fats 86 grammes, and carbohydrates 380 grammes (these ingredients being water-free); then the Harvey-Banting diet may be taken as—proteids 170 grammes, fats 10 grammes, carbohydrates 80 grammes. It is necessary that the *régime* be steadily adhered to for a considerable period, and recurred to from time to time when the weight shows signs of increasing. Several well-known modifications of this diet have been proposed. Ebstein's plan was based on—proteids 100 grammes, fats 85 grammes, carbohydrates 50 grammes, with 1,750 grammes of fluid, being an amount of proteids much below the normal, while the fats are of the healthy quantity. The deficiency of proteids tends to prevent this diet being pursued for long without loss of strength, and it would be probably more economical if rather less fat and rather more starch were allowed. Oertel's system is characterised by a marked restriction of fluids, the dry proteids being 170 grammes, fats 44, and carbohydrates 114 grammes. The reader will determine for himself how these proportions of alimentary principles may be distributed among various ordinary articles of diet. The exact influence of an excess of water in tissue-metabolism is uncertain, but there is no doubt that a large number of fat people consume an excessive amount of fluid, of which it may not be forgotten that alcohol forms very frequently a considerable proportion, and on such grounds a restricted intake might be regarded as desirable. But while cases of obesity associated with anaemia may be benefited by this treatment, it must be admitted that dehydration is attended with great risk in plethoric persons, especially if the nitrogenous food exceed or even equal the normal quantity, since serious disorders may result from accumulation in the tissues of their products of waste, from lack of fluid to flush them out. Still more is this the case in those extreme methods of dieting which consist of a practically unlimited amount of meat food, with complete abstinence from fats, starches, and sugars; and with such regimen a large allowance of hot water is insisted on. This plan, known as the Salisbury treatment, has been pursued with considerable success. This method consists in a daily diet of about 3 lbs. of lean beef, roasted or boiled, equally divided between the three meals, for a week or ten days, after which chicken or white fish may be given for a similar period, and then fats and later farinaceous foods are very gradually added. The fact is that each plan has its merits and can claim successful results, but judgment is requisite in its application to individual cases. All methods compel a very great decrease from the normal of starches, but on each of the other alimentary principles much diversity of practice exists. It cannot, however, be too strongly insisted on that for any considerable increase in nitrogenous food the kidneys must be in a perfectly healthy state, and this should only be permitted in conjunction with a free exhibition of water and a regular examination of the urine. Alcohol generally should be avoided, but especially spirits and beer, which must be absolutely forbidden, except on emergency; cider or the light dry wines, both white and red, diluted with water, are less objectionable. Tea and coffee are supposed to interfere with tissue-change, and therefore should be taken sparingly; and milk, from the quantity of fat it contains, is to some extent inadmissible, although a skimmed-milk diet has been proposed.

Regular exercise, within the limits of the patient's power, such as riding, walking, rowing, and gymnastics, is of great benefit by directly inducing an increased oxidation of tissue, and improving the quality of the blood, and therefore its oxygen-carrying power. It should form an essential part of every system of treatment, the amount being determined by the state of the patient's heart. When exercise cannot be taken, passive movements and massage should be employed. Cold bathing, if well borne, is of advantage on similar grounds. Free sweating by Turkish baths is a useful adjunct to dietetic treatment, unless the circulation be enfeebled. Breathing compressed air with the object of increasing the tissue-oxidation has been recommended.

It is in carrying out a system rather than in devising one that the difficulty occurs. The regularity and restraint prove irksome to the patient, and are frequently broken. Hence it is that the regimen and spare diet of the various spas, such as Carlsbad, Marienbad, Kissingen, and Ems have great advantages, since at such places and in such surroundings the patient more readily and willingly pursues a given plan.

In the treatment of intercurrent diseases it is essential to remember the enfeebled resisting power of the patient and the frequent necessity for stimulants.

Among the many drugs that have been used for obesity may be mentioned alkalis, iron, and iodine. Some of the good effects of the various 'waters' are ascribed to their alkaline properties, especially the alkaline aperients of the above-mentioned spas. Iron is an essential in those forms of corpulence associated with anaemia, and most satisfactory results follow its administration, as the health improves and the fat diminishes. Young chlorotic subjects benefit by this treatment, which may be advantageously carried out at some chalybeate spring, such as Tunbridge Wells, Harrogate, or Spa. The iodides, such as those of potassium and iron, given in large doses, undoubtedly effect a reduction in the amount of fat, but not always with a corresponding improvement in health. So long as this does not suffer and the patient improves, the drug may be persevered in, but it is frequently very badly borne when taken in quantity. The preparations of *Fucus vesiculosus*, the basis of certain quack remedies, appear to depend for their value on the iodine contained in them. The extract of the thyroid gland has been found useful in some cases, especially those of distinctly neurotic association. W. H. ALLCHIN.

OBLADIS, in the Tyrol.—Earthy saline waters and climatic health-resort.

OBSESSION (*ob*, opposite; *sedere*, to sit).—Formerly used to imply the state of a person supposed to be besieged by an evil spirit antecedent to possession. This term is now employed in psychological medicine to indicate the sudden occurrence in consciousness of an emotion or an idea dominating the mind, over which the individual has no control, and which may end in a sudden impulsive act which cannot be inhibited by the will. *See* INSANITY: *Imperative Ideas*.

OBSCULESCENT (*obsolesco*, I grow out of use).—A term applied to tubercular products which have dried up, shrunken, and become calcified and inert. *See* TUBERCULOSIS.

OBSTETRICAL PARALYSIS. — See BRACHIAL PLEXUS, Lesions of; and CEREBRAL DIPLEGIA.

OCCUPATION-DISEASES. — By the term 'Occupation-disease,' we mean disease directly traceable to the effects of a particular trade in which a person is engaged. As artisans are equally liable to the ordinary ailments of humanity, it is necessary to discriminate carefully so as to eliminate all causes other than those related to the particular industry in question. In the production of occupation-disease there are usually several factors in operation. Even in the causation of such an indisputable malady as lead-poisoning it is well to remember how important is the part played by individual idiosyncrasy, while in the better ventilated state of one factory compared with another, the home-life and surroundings of the workpeople, poverty, heredity, age and sex, are to be found conditions that are contributory to its production, and therefore not to be ignored. See PUBLIC HEALTH.

Arsenic and Colour-Grinding. — In the smelting of ore containing arsenic and in the manufacture of Scheele's green—an arsenite of copper used for colouring toys, artificial flowers, and wall-papers—workmen are sometimes seriously affected. Men who grind and mix arsenical colours often suffer from ulceration of the skin on those parts of the body with which the arsenic comes into contact. There is developed a painful form of eczema (p. 421). Beginning as vesicles the spots soon become pustular, and are extremely irritable. When an individual is exposed for any period to the dust arising from arsenical compounds, he often experiences a dryness and irritation of the lining membrane of the throat and nose, loss of appetite and indigestion, colic, and the passage of mucus in the stools. He loses flesh, and his eyes look congested. The urine may contain albumen, and there may be painful paralysis of the legs owing to peripheral neuritis. When once arsenic is in the system it is only slowly eliminated from it. Hence it is found in the urine long after the symptoms of poisoning have begun to decline. In the form of an alkaline arseniate it is used to dye wool. The girls who noddle and handle the dried wool thus treated inhale the irritating particles that are given off, and have been known to suffer from general ill-health, digestive derangements, and loss of power in their legs. Sempstresses who are in the habit of heedlessly biting off the ends of thread thus dyed, and men engaged in the manufacture of sheep-dipping washes, have also suffered in a similar manner. See pp. 1077-1078.

Cases of industrial arsenical poisoning observed by medical practitioners must be reported to the Home Office. See ARSENIC, Poisoning by.

Compressed Air.—See CAISSON-DISEASE.

Electricity.—Since the introduction of the electric light, and the employment of electricity in an increasing variety of ways, several fatal accidents have occurred. In the act of repairing wires, the cleaning of machinery, and accidental contact with charged parts of dynamos, workmen have received shocks that have proved immediately fatal. Occasionally the injuries received have been of a slighter character, and, for the most part, burns. An individual runs a very serious risk when brought into personal contact with conductors charged to a high pressure, say 1,000 volts; contact with even

240 volts is known to have caused death. As the result of a series of experiments, carried out by Professor Weber of the Polytechnic at Zurich, with the view of deciding what pressure is dangerous on electric railways with overhead trolley-wires, it was ascertained that to touch both poles of an alternating current circuit, where the pressure exceeded 100 volts, was not free from risk; but as there is little chance of passengers or other persons coming into contact with both the leads of the apparatus, the authorities decided to allow a working pressure of 750 volts, the current to be alternating. Apart from electrical pressure there are circumstances that tend to magnify the danger from contact, such, for example, as a workman standing on damp ground or wearing damp boots. If, on the other hand, he is standing on an indiarubber mat, which is a non-conducting material, he might possibly touch a single object, charged to a high pressure, without any harm following. Alternating and direct currents are equally dangerous.

It is not exactly known how electricity kills, but in all probability it is in one of two ways, either (1) by arresting breathing, or (2) by suddenly stopping the heart's action. R. A. Bolam and the writer carried out a series of experiments on anæsthetised animals with the view of throwing some light upon this question. Where high-pressure currents were used the animals were killed immediately. The heart suddenly ceased beating, but respiration was frequently continued for a minute or more afterwards. Although in most of our experiments death was due to sudden arrest of the heart's action, it was not always possible to say upon which organ or nerve-centres the current exerted its harmful influence. Sometimes we were able by artificial respiration to resuscitate an apparently dead animal, and there is no doubt that in the case of all persons who have received an electric shock and in whom life is apparently extinct, artificial respiration is the line of treatment that holds out the greatest promise of recovery. It should be undertaken immediately and persisted in for more than an hour afterwards.

Fatigue-Neuroses.—Over-use of the muscles and strain in certain occupations are apt to be followed by painful spasms or cramps, and occasionally by paralysis of particular muscles. In the production of these there is probably both a muscular and a nervous element in operation. While lengthened but interrupted employment of muscle through increasing the blood-supply improves nutrition and induces muscular hypertrophy, too protracted use, on the other hand, and overstrain, particularly if accompanied by the evil effects of working in a close atmosphere, cause breaking down. Spasm, tremor, or paralysis of muscle may thus be induced. It is customary to speak of either of these as *occupation- or fatigue-neuroses*, and in employing these terms we are not committing ourselves to any expression of opinion as to the pathological nature of the affection. There is an obstinacy or persistency about these neuroses that often defies treatment and makes their recovery tedious; also the muscular atrophy that is induced shows a tendency to get worse: circumstances that raise the question whether the affection in some instances at least should not be considered as outside the pale of a purely functional disorder. The morbid anatomy that underlies the condition is not known. As the industries of the country keep on multiplying and

machinery of a complicated character is introduced, requiring delicate manipulation and constant attention on the part of the worker, there is a corresponding increase in the number of fatigue-neuroses. These neuroses more or less resemble each other in the manner in which the different causes have operated to produce them. In *writer's cramp*, which is elsewhere separately dealt with, the excessive use of the pen is responsible for its production, and not the fact of the pen having been made of steel, as some persons suppose. The hurry and worry of modern life, and the high tension of the nervous system, are factors in its causation that cannot be ignored. In *file-makers*, who cut the tools by hand, paralysis and atrophy of the small muscles of the hand occur; and while plumbism is the prevailing cause in operation, some of the effects may be due to fatigue, especially the loss of power in the left thumb and forefinger which tightly grip the chisel, and the muscles of the right hand which wield a heavy hammer all day when at work. Plumbism and muscular fatigue are therefore both in operation in file-makers' paralysis. See WRITER'S CRAMP.

Clergymen and public singers who use their voice too much may overstrain the delicate muscular mechanisms concerned in vocalisation so that there is a sudden stoppage of the voice in public utterance owing to spasm of the glottis, or the voice becomes tremulous. In other instances there is aphonia so complete as to suggest a possible hysterical origin for the defect. Fatigue of laryngeal muscles is responsible for these attacks, which are in no way dependent upon catarrhal conditions of mucous membrane. When aphonia and globus co-exist the affection is neurotic in all probability. Rest from the use of the voice is a necessary part of the treatment. Bromides and Nux Vomica are useful; electricity may be tried, and change of air and scene recommended.

Typists, persons who work the Morse- or other telegraphic instrument and those who play the piano or the harp, occasionally find that the fingers and hands, owing to the excessive strain imposed upon them, refuse to carry out voluntary movements, and that the muscles become tremulous or are thrown into a state of spasm and do not relax readily. The spasm may be perfectly painless, but, occurring as it does at inconvenient moments, it worries the individual and prevents him accomplishing his task. Sensation is not affected. There may be no actual paralysis of muscle, but there is usually a degree of paresis that prevents co-ordinated movements being readily carried out. Usually the muscles respond to electricity. The battery is therefore well worthy of a trial in these cases along with massage and nerve-tonics. During treatment stimulants should be avoided.

The writer has seen a few instances of atrophy of the muscles of the left shoulder in railway surface-men due to the habit of these men carrying their heavy implements on their shoulders. No doubt exposure to wet and cold also has its influence. The affection sometimes resembles progressive muscular atrophy although it is due to a neuritis. *Bricklayers* from prolonged grasping of the trowel in the right hand sometimes suffer from muscular spasm.

Miners' Nystagmus.—Coal-miners occasionally exhibit a very marked oscillation of the eyeballs in a lateral or rotatory direction when asked to fix

their attention on any particular object, and which obliges them to put their ocular muscles on the stretch. Tremor is then noticeable. This tremor may cause very little inconvenience in some men, but in others it is associated with vertigo. The objects looked at appear to be unsteady. In miners of a nervous temperament nystagmus rather aggravates any neurotic tendencies. The oscillatory movement of the eyeballs is attributed to strain of the muscles of accommodation and convergence caused by the miner working in the flickering light of his Safety lamp. Secondary oscillations of the head are often present. Simeon Snell, of Sheffield, finds that nystagmus only occurs in men who are working in narrow seams of coal, and who in the act of hewing the coal lie on their side with their eyes cast in an upward and oblique direction, thus imposing a lengthened strain upon the levator palpebræ, superior rectus, inferior oblique and external rectus muscles of one eye, with the same in the other, except that the internal rectus is involved instead of the external. In Newcastle-upon-Tyne nystagmus was some years ago very prevalent among coal-miners, but during the last fifteen years it has become much less frequent. Since nystagmus occurs in such diseases as insular sclerosis and Friedreich's ataxia, it is necessary to distinguish between that due to strain of the ocular muscles met with in the coal-miner and those forms arising in the course of cerebro-spinal disease. The history of the case, the age of the patient, and the absence of affections of speech would assist in the diagnosis. In coal-miners' nystagmus there is no evidence of disease of the brain or of the nervous system. It is solely due to fatigue of the external muscles of the eyeball. See NYSTAGMUS.

Gas in Coal-Mines.—When an explosion has occurred in a coal-mine, and has been attended by fatalities, it has generally been believed that the death of the victims has been the result of shock or extensive burns of the body. In a certain percentage these two causes have been in operation, but there is no doubt that many of the colliers meet their death by inhaling the 'after-damp'—a gas that is rich in carbon monoxide. The proof of this is the ruddy colour of the skin of the cadaver, also that on spectroscopic examination of the blood two bands are observed between D and E, in the yellow and the green, which are not, like those of oxyhæmoglobin, affected by adding ammonium sulphide. Apart from explosions the coal-miner is constantly running the risk of inhaling carbon di-oxide, or 'choke-damp.' This is the gas which makes its presence known to the collier by his lamp becoming extinguished, and by a feeling of slight embarrassment of his breathing. Wherever in a coal-pit a miner's lamp cannot burn, it is evident that human life cannot for long be maintained. Education and experience inform him that it is then time to retire. The miner is thus forewarned of the danger of *choke-damp*, but he has no such warning of the presence of carbon monoxide. It is the presence of this *after-damp* in a coal-mine, after an explosion, that makes it dangerous for a rescuing party to descend. Men who are brought into contact with this gas are insensibly overcome by it. They become drowsy and extremely languid, and by degrees pass into a state of unconsciousness. The presence of even such a small quantity as one per cent. of this gas will cause unpleasant symptoms. Ten per cent. has proved fatal. See DYNAMITE-POISONING.

TREATMENT.—After a colliery explosion fresh air should be got as rapidly as possible into the mine, for although colliers may have been rendered unconscious by the carbon monoxide, yet death may not supervene for an hour or more. Cylinders of oxygen should be taken into the mine, the sufferers should be brought to bank as quickly as possible, warm blankets applied, and stimulants very carefully administered. Above all, artificial respiration must be carried on, and a hypodermic injection of strychnine is worthy of a trial.

Glass-makers and Glass-blowers.—The risks incurred by glass-makers are those due to exposure to high temperature, e.g. bronchial and pulmonary affections, and also cataract. Occasionally glass-blowers develop a cystic swelling of the cheek, due to air passing up the duct of the parotid gland; thickened patches of mucous membrane inside the mouth and cheek; and also deafness.

High Temperature and Muscular Strain. Men who are employed at the blast furnaces of iron-works, in addition to running risk from burns and irritating particles of dust settling on their eyes, are, owing to exposure to heat and cold, liable to bronchial and pulmonary affections and to rheumatism. When young the men as a class are physically strong. Their work is hard and their wages are good. They are able to buy good food, therefore they eat well, but later on they take to drinking stimulants rather freely, and, as their work is arduous, the free consumption of alcohol tends to make them break down and to cause them to become prematurely old.

Men who are employed at the *puddling* furnaces are exposed to very severe muscular strain and excessive heat, and consequently, even in the winter months, they work with very little clothing on. As they perspire very freely they imbibe all sorts of liquids to replace the loss. A very large number of puddlers develop heart-disease, particularly commencing at the root of the aorta, owing to the strain put upon the aortic valves. Puddling is generally regarded as one of the most degrading kinds of work in the iron-trade. Since steel is now very largely taking the place of iron, puddling is much on the decline. It is not required in the manufacture of steel, and as a consequence heart-disease in iron-workers is now less frequently met with than formerly. See *HEAT, Effects of*.

Indiarubber.—Makers of indiarubber goods, especially of the finer variety, are liable to illness of rather a serious character. In order that indiarubber may be able to withstand variations of temperature it has to be vulcanised by being passed through bisulphide of carbon. During this process the vapour of the bisulphide is inhaled and it causes intoxication. This may assume a form of drunkenness not unlike that caused by alcohol, in which the individual staggers and even falls; or the symptoms are less acute, and the individual complains of headache and indistinct vision, or is the subject of epileptiform seizures or muscular tremor. Some of the workers lose the power of their legs owing to peripheral neuritis, others suffer from double foot-drop, while others become ataxic. In a few instances the workers when intoxicated have become acutely maniacal. Treatment resolves itself in the minor form of intoxication into removal of the individual from his occupation, and in the severer forms of illness into the treatment of symptoms.

Lead and its Compounds.—Lead is so largely used in the industries that plumbism occurs unexpectedly in people whose occupation sometimes does not suggest immediate contact with the metal or its compounds. Silk thread, for example, is occasionally passed through a solution of acetate of lead to increase its weight. Sempstresses who are in the habit of biting off the ends of the thread are known to have suffered from colic and general ill-health. The sweet taste of the thread ought to forewarn them of the danger. White lace is, on the Continent, sometimes whitened by carbonate of lead.

File-cutters are especially prone to plumbism. The men and women cut the files upon a leaden cushion. A considerable amount of metallic dust is given off which becomes oxidised. Some of this may be inhaled, but as the occupation is a dirty one, and the workpeople as a class are not cleanly and often eat their food with unwashed hands, the probability is that the poison also gains an entrance into the system through the alimentary canal. Colic and muscular paralysis frequently occur. The symptoms of plumbism develop slowly. Health is gradually undermined, albumen appears in the urine, and the individual succumbs to the effects of a chronic interstitial nephritis. In the United States all files are made by machinery, and as a consequence plumbism among file-makers is unknown. In Sheffield, the centre of the industry, efforts have been made to supplant hand-made by machine-made files, but with only qualified success, for the customs of a trade die hard.

Plumbers who handle metallic lead and use the carbonate for jointing purposes; *printers*, especially *compositors* who set the type; and *house-painters* are all liable to lead-poisoning. Medical men are obliged according to the requirements of the Home Office to notify to the Chief Inspector of Factories cases of industrial lead-poisoning occurring in their practice. House-painting, since it is carried out in the open air, scarcely comes under work done in a factory or workshop, although it might possibly come under the latter. Notification of plumbism in house-painters is, however, accepted by the Home Office, and the usual fee of half a crown is given for each case reported. It is only since notification of lead-poisoning has taken place that we have realised how prevalent is plumbism in this trade. During the month of July 1900 there were 12 cases of plumbism in house-painters reported to the Home Office, one of which proved fatal. In Paris, according to Gautier, house-painting is a prolific cause of plumbism. Of 86 fatal cases of lead-poisoning that occurred in the French capital, during 1894-8, 43 were painters, and out of 14,000 painters and varnishers, Gautier found 250 were annually in the hospital. Statistics have only begun to be kept in our own country. During 1899 upwards of 100 cases of plumbism in painters were voluntarily reported to the Home Office, and of these 18 were fatal.

House-painters become poisoned by handling and mixing the colours, possibly too, although less likely, by inhalation of the terebinthinated vapour arising from the paint, but principally by the fume while burning off the old paint or in smoothing a recently painted surface with sand-paper.

Coach-painters similarly suffer, also men who are employed to break up and burn old railway-carriages.

Glass-polishers use what is called in the trade putty-powder, but this contains frequently as much as 60 per cent. of white lead. In the act of polishing glass a considerable amount of spluttering takes place upon the clothes and hands of the workman and the floor of the workshop. On this material becoming dried, dust is given off, which rises into the atmosphere and is inhaled. Colic and paralysis are therefore not unknown among glass-polishers.

In the *enamelling of iron-plates* for advertisement purposes a large amount of lead is used, and during the dusty process known as 'brushing-off' the girls inhale the powder, and frequently suffer in consequence. Some departments of *white-lead making* are extremely dangerous. See LEAD, Poisoning by.

Pottery.—Lead-poisoning in potters is extremely common. The glaze in which earthenware is dipped frequently contains as much as 30 per cent. of white lead. The men who dip the ware, the girls who clean it, the men who place the ware in the kilns and who are known as glaze-placers, the individuals who make the litho-transfers—the coloured papers used for imprinting colours upon china—colour-dusters and majolica-paintresses run the risk of suffering from lead-poisoning. So prevalent, indeed, had plumbism become in the Potteries that Professor Thorpe and the writer were entrusted by the Government with the task of reporting upon this industry, and of suggesting measures for the diminution, and, if possible, suppression of lead-poisoning. Among other things we recommended the total prohibition of raw lead, i.e. the use of white lead, in the glazes, and the employment of 'fritted' compounds. These suggestions, if put into force, would of themselves cause a very marked diminution in the amount of plumbism. The removal of females from the dangerous departments, and repeated medical examination of all workers in the lead processes, are also measures that would make for health. These, with the recommendations previously mentioned, have the unanimous support of the manufacturers. It is otherwise, however, with the suggestion that leadless glazes should for the most part replace those that contain lead. Only by such a substitution is it possible to render certain processes in the manufacture of earthenware healthy to the workpeople.

Mercury.—*Felt-hats*.—In the manufacture of hats a strong solution of nitrate of mercury is used to promote the felting of the fur. The workmen who handle and shape the felt run the risk of becoming salivated, and occasionally they suffer from the constitutional effects of mercury, including tremor. The danger mostly occurs after the fur is dried, for it is then that dust is given off.

Mirror-makers.—Formerly when mercury was employed in the manufacture of mirrors the workmen suffered from hydrargyria, but since the introduction of the new method of employing nitrate of silver and tartaric acid, mercurial poisoning has disappeared.

Cases of industrial mercurial poisoning must be reported to the Home Office.

Nitro- and Di-nitro-benzole and Aniline. Nitro-benzole is used in the preparation of perfumery, the manufacture of aniline, and of certain high explosives for mining purposes. Nitro-benzole when treated with nitric and sulphuric acids at a high temperature becomes di-nitro-benzole. This substance acts as a poison, whether it is absorbed by

the skin or inhaled. The men who work at the trade experience a heavy sleepiness; they complain of throbbing headache and vomiting, and when the symptoms are more severe, there are dyspnoea and cyanosis, dilated pupils and an ataxic gait. The urine becomes reddish-brown, and both from it and the breath of the workman there is given off the odour of bitter almonds. Coma and symptoms of cerebral apoplexy with Cheyne-Stokes' breathing have been observed. The skin becomes dark blue owing to the presence of aniline. The blood exhibits a dark chocolate colour, loses its power of absorbing oxygen, and gives the spectrum of methæmoglobin. Fifteen drops of nitro-benzole when swallowed have caused death. When injected into the veins of an animal it causes death almost as rapidly as prussic acid, and in acute poisoning there is, strange to say, an odour of prussic acid. These two forms of poisoning resemble each other, but when the two substances were administered by the mouth to animals symptoms of hydrocyanic-acid poisoning came on at once, but those due to nitro-benzole were delayed for a brief period.

TREATMENT is to wash out the stomach, apply mustard-poultices to the chest, administer such a stimulant as ammonia, perform artificial respiration, and apply the faradic current.

Aniline is obtained from coal tar and naphtha. It is a narcotic poison, and acts upon the central nervous system, causing insensibility, convulsions, and motor paralysis. The workmen complain of headache and vertigo, and suffer from spasms. Aniline destroys the blood-corpuscles, and forms methæmoglobin. The urine becomes brownish-black, and the skin is often the seat of eruptions (p. 70).

Phosphorus and Lucifer Match-making. Two kinds of phosphorus are used in the manufacture of matches, the red and white. The red or amorphous phosphorus can be handled without risk. It is used in the manufacture of safety matches. White or yellow phosphorus is so inflammable on exposure to the air that it has to be kept in water. It emits fumes which are luminous in the dark. In the act of glowing phosphorus is being oxidised. The fume itself is one of the lower oxides of phosphorus. Most of the white phosphorus used at home and abroad is made at Oldbury, near Birmingham, and although it is a dangerous industry the processes are carried on so much under cover that it is only very rarely men have been known to suffer. In the manufacture of matches the danger is manifold. It is seldom that there is more than 5 per cent. of white phosphorus present in the paste for heading matches. The men who mix the paste in open iron basins, the men who dip the matches, and the girls who 'box' the dried matches inhale the fumes of phosphorus, and as a consequence some of them suffer from necrosis of the jaw-bone. This is apt to be a chronic affection. Attended at its commencement by a good deal of pain owing to the formation of an abscess at the root of a tooth, pain subsides when once the tooth is extracted and a free vent given to the pus. Disease of the bone progresses slowly. It may continue for months or years, and as the purulent discharge escapes into the mouth and is swallowed ill-health and pulmonary disease are induced. When the necrosis affects the upper jaw it is not unusual for the inflammation of the bone if virulent to extend to the base of the skull and set up a purulent meningitis or cerebral abscess. For-

merly in France match-makers suffered from a constitutional form of poisoning known as *phosphorism*, the principal features of which are anæmia, digestive derangements, and albuminuria. This form of the malady has been seldom observed in England, and yet both here and on the Continent, while we are most familiar with its local effects, viz. phosphorus-necrosis or 'phossy-jaw,' a constitutional state of a peculiar kind is developed whereby without any actual traumatism the long bones readily undergo spontaneous fracture.

There is diversity of opinion as to how phosphorus-necrosis is caused. It is generally held that there must be a pre-existing caries of a tooth; and that through the decayed tooth the fumes of phosphorus make their way to the jaw-bone, setting up a periostitis which soon becomes septic. How far necrosis is the result solely of the action of the irritating fumes of phosphorus it is difficult to say. The disease if induced in the first instance by the oxides of phosphorus is certainly later on aggravated by the presence of microbes. Professor Stockman of Glasgow found tubercle-bacilli in the purulent discharge escaping from the necrosing jaw of affected match-makers, and is disposed to regard the lesion as tubercular.

Prevention of phossy-jaw.—The mixing of white phosphorus should be conducted in closed vessels. The dipping of the matches should be done on slabs, on the distal side of which there should be a fan; the boxing of matches should be accomplished by machinery in preference to hand, but if by hand the boxing should be carried on in front of ventilating shafts, up which the fumes can be drawn away from the worker. The hands of the workers should be well washed before eating, and no food should be eaten in the factory. Overalls should be worn, and since turpentine stops the oxidation of phosphorus, terebinth gargles may be used. There should be repeated dental examination, and on the slightest development of pain in the gums and teeth the worker should be removed at once. Weakly persons with an heredity of tubercular disease, and those who are intemperate, ought not to be allowed to work in the dangerous processes of a match-factory. The treatment of phossy-jaw is surgical. In this country Garman obtained good results by expectant treatment, and the use of antiseptic washes. The cases are tedious. There is little deformity left.

All cases of industrial phosphorus-poisoning must be reported to the Chief Inspector of Factories, Home Office.

Pressure-diverticula (*Pharyngocœles*) are described under PHARYNX, Diseases of. See also PAIN IN VISCERAL DISEASE.

1. Examination of the Œsophagus.—

Methods of examining the gullet by means of the œsophagoscope and auscultation have been introduced, but their utility is so questionable that they will not be described. The bougie is the instrument which gives the only reliable information regarding the condition of the tube, and in every case an olivary bougie with a large bulbous extremity and a narrow (preferably whalebone) stem should be employed. This instrument (*cathéter explorateur à boule*) is greatly superior for diagnostic purposes to the cylindrical bougie generally employed, as localisation of the site of a stricture is much more exact than can be the case with a cylindrical instrument. Certain measurements in connection with the œsophagus must be kept in mind. $15\frac{1}{2}$ to 16 inches is the average distance from the incisor teeth to the cardiac opening of the stomach; $9\frac{1}{2}$ to 10 inches of this measurement corresponds with the length of the œsophagus, and 6 inches to the average distance from the incisor teeth to the commencement of the œsophagus. If the examining bougie pass for a distance of 16 inches or more from the incisor teeth the surgeon may conclude that it has traversed the whole length of the œsophagus and has entered the stomach. Prior to passing an œsophageal bougie the pharynx may be sprayed with a 2-per-cent. solution of cocaine. The instrument, warmed and moistened with glycerine, must be passed down the posterior wall of the pharynx. If, as is commonly the case, the passage of the bougie is temporarily arrested at the pharyngo-œsophageal junction, the patient should be requested to try to swallow it. This manœuvre generally overcomes the obstruction.

2. Foreign Bodies.—Foreign bodies in the œsophagus may be of the most varied kinds. They may be swallowed by accident or by design, as in the case of jugglers, as well as by insane patients. Artificial teeth, coins, and fragments of bone are among the commonest objects found. Such bodies are apt to lodge in those parts of the tube in which the lumen of the œsophagus is naturally constricted, viz. (1) its commencement, just behind the larynx; (2) a point just above the junction of the upper and middle thirds; and (3) at the lower end, just above

the diaphragmatic opening. The symptoms are dysphagia, pain at the site of the obstruction and sometimes cough, with regurgitation of part of the food swallowed, and later on discharge of blood and pus without cough or vomiting. Digital exploration of the pharynx may detect a foreign body impacted near the commencement of the gullet, and a bougie will demonstrate the presence of one lower down. The majority of foreign bodies, including coins, bones, and gold tooth-plates, may be strikingly localised by the Röntgen rays. Of the many ingenious instruments designed for the removal of foreign bodies in the œsophagus the safest and best is the horse-hair probang, which may be in most cases passed by the side of the offending body and then opened out. As it is withdrawn it pushes the foreign body in front of it. Should simple measures fail, the gullet may have to be opened (*œsophagotomy*), since, if the foreign body be allowed to remain impacted for several days, ulceration and perforation of the œsophagus will in all probability ensue.

3. **Rupture.**—This very rare and necessarily fatal accident may, it is said, occur in a previously healthy viscus as the result of violent vomiting, though probably some weakness or lesion in the tube has existed in the majority of instances. Intense pain, collapse, and death in a few hours follow the accident. The site of rupture is always in the lower part of the tube. This accident must not be confounded with the far more frequent condition of *post-mortem* digestion of the œsophagus.

4. **Acute Inflammation.**—Acute œsophagitis may occur from various causes. It is of interest in that it may lead to stricture, ulceration, perforation, and pericœsophageal abscess. It is found (1) in cases of scald and burns of the œsophagus, whether caused by boiling fluids, strong acids, or caustic alkalis; (2) in traumatic lesions due to the presence of foreign bodies; (3) in infants, in whom it may occur without apparent cause, or as an extension of an inflammatory process from the pharynx; (4) in the course of any of the specific fevers; and (5) in the last stages of wasting diseases, e.g. phthisis and cancer, especially cancer of the gullet itself.

The chief symptom is pain in swallowing, which may be rendered impossible, combined with tenderness on pressure over the gullet and spitting of tenacious mucus. Frequently, however, particularly in the mild catarrhal cases, the pain is so slight that in the absence of all other symptoms the acute œsophagitis is unsuspected. The catarrhal cases call for no treatment beyond the administration of bland fluid food. In aggravated types of the disease, e.g. in those due to swallowing strong caustics, feeding by the mouth must be discontinued, and nutrient enemata employed. In such severe ulcerative and gangrenous cases with great destruction of mucous membrane, cicatricial strictures of the worst kind frequently result.

5. **Chronic Inflammation.**—Chronic œsophagitis.—This is generally a sequel of the acute affection above described. Chronic inflammation is generally found to a greater or less degree above the site of a stricture, whether cicatricial or malignant, and is of great importance, in that it predisposes to ulceration and perforation of the gullet. In chronic drunkards a peculiar form of chronic œsophagitis is sometimes met with, associated with vomiting, chronic ulceration of the mucous membrane, and, it may be, with fibrous stricture.

6. **Ulceration.**—Not infrequently in wasting diseases small catarrhal ulcers are found in the œsophagus. They have rarely been met with in typhoid fever, syphilis, and tuberculosis. The cicatrization of simple ulcers may result in stricture of the œsophagus. Ulceration with perforation is common in advanced carcinoma.

7. **Pericœsophageal Abscess.**—This term is applied to a suppurative inflammation of the pericœsophageal connective tissue. The inflammation may originate in the œsophagus itself, e.g. ulceration and perforation (due to foreign bodies or carcinoma), or in the neighbouring lymphatic glands; or it may spread from some other focus of inflammation, e.g. retropharyngeal abscess or spinal disease. The œsophagus may be displaced in various directions dependent upon the place of origin of the abscess. The symptoms are pain in the course of the œsophagus, greatly aggravated by swallowing or movement of the head and neck and elevation of temperature. If the suppuration is diffuse death invariably ensues. If it is localised and is situated in the neck, incision will be indicated as soon as the presence of pus is suspected. A localised abscess, situated in the thorax, may burst into the gullet, the pus be vomited or swallowed, and recovery ensue. The diagnosis of pericœsophageal abscess is most difficult, and is generally only made on the *post-mortem* table.

8. **Syphilis and Tuberculosis.**—(a) Syphilis attacks the œsophagus but rarely, and then always in the tertiary stage. Localised gummata or gummatous infiltrations are found in the mucous and submucous coats of the viscus. Ulceration leading to cicatricial contraction is prone to occur. The symptoms are merely those of difficulty and pain in swallowing, and the diagnosis, except in cases in which tertiary syphilis is manifestly active, is most difficult. In the earlier stages, i.e. before cicatricial contraction has supervened, iodide of potassium in full doses will rapidly relieve the symptoms.

(b) Tubercular disease of the œsophagus is very rare. In a few instances multiple ulcers have been found in the œsophagus near its cardiac extremity, surrounded by a zone of submucous induration, and in the majority of cases in conjunction with tubercular ulceration of the intestines or in advanced tuberculosis of the larynx. Their presence might be suspected if in a case of advanced tubercular disease pain in the lower part of the œsophagus became a marked symptom on deglutition.

9. **Varicose Veins.**—In obstruction to the portal circulation, particularly in cirrhosis of the liver, the veins in the lower two inches of the œsophagus may become extremely dilated and varicose. Severe or even fatal hæmorrhage from bursting of such varices is not uncommon. See HÆMORRHAGE.

10. **Cicatricial Stricture.**—Stricture of the œsophagus due to cicatricial narrowing of the lumen of the tube is the result generally of injury caused by burns from hot fluids or caustic substances (acids or alkalis), less frequently of the traumatism caused by the lodgment of a foreign body, and rarely of the healing of syphilitic, tubercular or typhoid ulceration. In addition to cicatricial stricture malignant tumours infiltrating the wall of the tube produce great narrowing of the lumen of the œsophagus, and, in fact, cancerous stricture is far more common than the cicatricial variety. Congenital malformation is a rare cause of innocent stricture. Pressure from without, as in the case of an aortic aneurysm or media-

stinal tumour, may produce symptoms indistinguishable from those of true organic stricture. Cicatricial stricture may be annular or may extend to several inches in length, and while it may be found in any segment of the gullet it is commonly either at the uppermost or lowermost part of the tube. The diminution of the calibre may be slight or may be so extreme that even fluids can scarcely pass through the stricture. The œsophagus above the stricture generally becomes dilated and its wall hypertrophied, and thus a cavity results in which food, partly-altered by the action of the saliva, may remain for a considerable time before it is regurgitated. When of course the stricture is high up, i.e. near the pharynx, it is at once returned. The chief symptom in all cases is difficulty in swallowing. At first this is for solids only, later on fluids are swallowed if at all only with difficulty, and then regurgitation (false vomiting) of food occurs either immediately or after a varying period of time. The narrowing is progressive until at last deglutition becomes impossible, rapid wasting ensues and death from starvation threatens. The diagnosis is seldom a matter of difficulty. In general there is a history of injury or burn. The passage of a bulbous bougie indicates the site and amount of the constriction. Possible sources of error are pressure of tumours from outside the tube and œsophageal pouches. A careful examination of the chest so as to exclude aneurysm and mediastinal tumour should always precede the passage of a bougie.

TREATMENT.—The majority of cases of cicatricial stricture can be treated by gradually progressive dilatation with fairly satisfactory results. In impassable strictures gastrostomy must be performed. It is sometimes found that strictures which were impassable from above downwards admit of the passage of a bougie passed from the incision in the stomach. Permanent intubation of the œsophagus (*Symonds's tube*) has also been employed.

11. Dilatation.—Primary dilatation of the œsophagus is very rare. In the few instances recorded the middle segment was chiefly affected and a spindle-shaped dilatation produced. Hypertrophy of the muscular wall was also present. It has been suggested that these cases were examples of spasm of the cardiac orifice of the stomach which, of course, would disappear after death; but against this explanation is the fact that it is not the lowest part of the tube that undergoes the greatest amount of dilatation. Secondary dilatation above a stricture is a far more common condition. It needs no treatment, except that of the stricture, to which it is due.

12. Tumours.—*Innocent tumours* are rare. Papillomata, mucous cysts, fibromata, and myxomata have been occasionally met with. These tumours tend to assume a polypoid character, and when situated near the upper limit of the œsophagus may be snared or avulsed by forceps.

Malignant Tumours.—Sarcoma is one of the rarities of medicine. Cancer of the œsophagus is unfortunately of common occurrence, and is most frequently met with between the ages of 45 and 60 years. It is four times as frequent in men as in women, and is as often found in the upper as in the lower segment of the gullet. Squamous epithelioma is the commonest variety, but in about 5 per cent. of the cases a spheroidal-celled carcinoma (encephaloid or scirrhus) is met with. The growth usually takes an annular form, and is

1 to 1½ inches in length. The tumour infiltrates all the coats of the gullet and, owing to the irritation caused by the passage of the food, ulceration sets in early. Not infrequently ulceration, by increasing the lumen of the tube, lessens the dysphagia temporarily. The earliest and chief symptom is dysphagia, which is increased by spasm. Regurgitation of food mixed with ropy mucus and perhaps with blood and particles of the growth soon sets in; and cough with foul breath is generally present. The course of the disease is very rapid, death supervening in a large majority of cases in from 6 to 12 months after the commencement of the dysphagia. The patient may die of inanition, of cancerous cachexia, of septic broncho-pneumonia, of gangrene of the lung, of septic pleurisy, or of perforation of the aorta or other large vessels with fatal hæmatemesis. The above complications are largely the result of extension of the ulcerative process to the bronchi, lung, blood-vessels and pleura. Extension to the lymphatic glands in the neck and chest is common, but secondary growths in parts other than the thorax are exceptional. In rare cases the patient may die of œsophageal cancer without having made any complaint of dysphagia. Pain is not usually a prominent symptom, but in some cases it is both extreme and constant.

The diagnosis in the early stages is sometimes difficult, and in the latent cases impossible. The early symptoms are those of stricture. It is therefore necessary to exclude cicatricial stricture and pressure from without (mediastinal growth or aneurysm). The presence of enlarged cervical lymphatic glands suggests cancer. The bougie demonstrates the existence of a stricture, but the instrument must be introduced with extreme care owing to the liability of the diseased wall to perforation.

TREATMENT.—In cancers situated at the upper end of the œsophagus excision is possible and has been performed with success. In inoperable cases (the large majority) permanent 'tubage' or gastrostomy must be undertaken as soon as swallowing becomes impossible. A flexible gum-elastic tube from 4 to 6 inches in length and funnel-shaped above is introduced, with the funnel resting on the stricture by means of a special introducer (*Symonds's tube*). In many instances this tube is not tolerated by the patient, and in impassable strictures it is useless. In such cases the operation of gastrostomy is to be performed, and will be found of the utmost benefit in prolonging life and appeasing the agonising pains of hunger. The common error is to delay this operation until the exhausted state of the patient renders any operative interference inadmissible.

13. Spasm.—*Œsophagismus.*—Spasmodic stricture is met with in hysterical young women and in men of neurotic tendencies. It must be distinguished from the spasm that so frequently co-exists with true strictures, cicatricial and malignant. The spasm generally commences during a meal, a bolus of food sticking in the œsophagus, and is accompanied by coughing, retching, and loud gurgling sounds. After a time the bolus of food is either rejected or passed on into the stomach. A burning pain is commonly felt at the site of the constriction.

Important points in the diagnosis are the co-existence of globus hystericus, the acute character of

the pain, the sudden onset of the spasm, and the varying position of the obstruction, as experienced by the patient and as detected by the sound. The site of the spasm may vary during a single examination. The spasm yields in almost every case to firm equable pressure and always relaxes under anæsthesia. The sound can often be withdrawn without encountering any obstruction on its return journey. The affection is troublesome rather than dangerous, and a high degree of emaciation is but rarely met with. The passage of a full-sized bougie, which may be repeated two or three times a week, is often curative. The neurotic state of the patient requires treatment, and must never be neglected. The drugs most generally useful are the bromides and belladonna, and, in markedly hysterical girls, valerian.

14. **Paralysis.**—Paralysis is but rarely met with. It occurs in diseases of the central nervous system, especially in bulbar paralysis. It may, however, be a result of peripheral neuritis as in diphtheritic paralysis and plumbism. Though sometimes stated to be of hysterical origin, it is very infrequently met with. In hysteria spasmodic stricture is much more likely to occur than paralysis. The prognosis and treatment depend on the cause. Faradic stimulation of the œsophagus has been recommended. In general the employment of the stomach-tube is necessary in order to feed the patient.

15. **Malformations.**—Pressure-diverticula (*Pharyngocœles*) are described in the article on the PHARYNX.

Congenital Malformations.—*Dilatation* has been already described. A *membranous stricture* is very rarely found in the young infant at the junction of the upper fourth with the lower three-fourths of the gullet. Infants have been born with a fistula connecting the œsophagus and the trachea. Death always supervenes in a few days or weeks from the entrance of milk into the respiratory passages and the supervention of septic broncho-pneumonia. An *imperforate œsophagus* is commonly due to the absence of one of the segments of the tube. It is excessively rare. The attempt to take the breast is followed immediately by a suffocative attack owing to the food being unable to enter the stomach, and therefore finding its way into the air-passages. Gastrostomy offers the only chance of saving life; but no successful case has been recorded.

Acquired Malformations.—*Traction-diverticula* result from inflammatory processes near the œsophagus, especially when these end in suppuration, and the subsequent shrinkage of the evacuated abscess-cavity. In these cases a part of the abscess-wall becomes adherent to the wall of the œsophagus, which is thus drawn out as a diverticulum. These traction-diverticula are commonly found about the bifurcation of the trachea, in which case they originate in inflammation of the lymphatic glands, and are seen springing from the anterior wall of the gullet. More rarely they are placed laterally. They tend to form pockets in which food collects and undergoes decomposition and introduce a serious fallacy; bougies introduced into the œsophagus are apt to get caught in a diverticulum. These traction-diverticula are not to be confounded with pressure-diverticula (*Pharyngocœles*). See PHARYNX, Diseases of.

HERBERT F. WATERHOUSE.

ŒSTRUS (ὄϊστρος, a gadfly).—SYNON. : Fr. *Œstre*; Ger. *Bremse*.—A genus of dipterous insects, called gadflies, the larvæ of which, vulgarly known as maggots or bots, live parasitically in man and animals. The ordinary human bot, *Œstrus hominis*, is of rare occurrence in England, but is not infrequently met with in warm countries, especially in South America. The larva of the gadfly of the ox, *Œstrus bovis*, also occasionally attacks man.

True maggots and other bot-like larvæ are occasionally encountered in medical practice. Livingstone, when in Africa, was attacked in the leg by a small bot-like larva, which was removed, and is now preserved in the museum of the Royal College of Surgeons of England.

OEYNSHAUSEN, or REHME, in Germany.

Gaseous thermal salt waters, closely resembling those of Nauheim. See MINERAL WATERS.

OÏDIUM ALBICANS.—SYNON. : *Saccharomyces mycoderma*; *Mycoderma vini* (Grawitz).—A vegetable parasite, associated with thrush. See MOUTH, Diseases of (p. 1030).

OINOMANIA (οἶνος, wine; and μανία, madness).—A synonym for dipsomania. See DIPSO-MANIA.

OLD AGE, Signs of.—See SENILITY.

OLFACTORY SENSE, Morbid Conditions of.—The principal morbid conditions that occur in connection with the sense of smell are the following: (1) Hyperæsthesia; (2) Subjective Sensations of Smell; (3) Perversion of the Sense of Smell; and (4) Olfactory Anæsthesia.

1. **Olfactory Hyperæsthesia.**—SYNON. : Hyperosmia.—This condition is seen in the increased nervous sensibility which results from chronic debilitating illness. It occurs also in hysteria, in which remarkable, almost animal, acuteness of the sense is sometimes present, so that not only objects but persons have been discriminated by this means. In insanity the same condition is sometimes met with. A less degree of olfactory hyperæsthesia is occasionally met with in epileptics and persons suffering from myxœdema. It is usually associated with, and has to be distinguished from, an altered appreciation of odours, shown in the abnormal enjoyment of or disgust at the odours which are recognised with natural or preternatural acuteness. The condition is probably of central origin and rarely calls for special treatment.

2. **Subjective Sensations of Smell.**—Subjective sensations of smell occur from central disease, or from irritation of the nerve of smell. In the insane, olfactory hallucinations occur, though less commonly than those of the visual or auditory sense. Schlager met with them in five cases out of six hundred. In epilepsy subjective sensations of smell occur as occasional prodromata of fits, and the disease in these cases probably involves the olfactory centre in the anterior part of the temporal-sphenoidal lobe. It was so in a case of tumour recorded by Sander. Irritation of the nerve from meningeal disease or injury also, in rare cases, causes olfactory hyperæsthesia. Persistent disagreeable smells are occasionally complained of after influenza.

3. **Perversion of the Sense of Smell.** SYNON. : Parosmia.—This is a rare condition which

occasionally results from irritation of the nerve or central organ. In a case recorded by Legg, some time after an injury to the head, all substances 'tasted' of gas or paraffin, and there was marked diminution in the acuteness of the sense of smell.

4. **Olfactory Anæsthesia.** — **SYNON.** : Anosmia.

DEFINITION.—Loss or diminution of the sense of smell.

ÆTIOLOGY.—The causes may be local changes in the organ of smell; disease of the nerve; or disease of the centre.

(a) Among *local* causes may be mentioned the following: (1) Acute and chronic catarrh of the olfactory mucous membrane, the latter causing thickening—a condition sometimes produced by excessive snuff-taking. A large proportion of the cases follow severe and prolonged catarrh, and are due purely to the local effect on the tissues through which the olfactory nerve-endings are stimulated. (2) Dryness of the mucous membrane, as in cases of destruction of the external nose (Notta), or in paralysis of the fifth nerve. (3) Occlusion of the passage by polypus, preventing the access of air to the olfactory region. (4) Impaired access of air consequent on facial paralysis. The loss of the power of dilating and keeping expanded the nostril prevents a due quantity of air being drawn through the nasal passage; and, moreover, the loss of power of compressing the nostril in 'sniffing' prevents the air being directed into the olfactory region. (5) In rare cases loss of pigment in the nose, consequent on general loss of pigment, has appeared the cause of loss of smell.

(b) *Damage to the olfactory nerve* may result from injury or disease. It is not an uncommon result of blows or falls upon the head, and it is probable that in these cases the delicate olfactory nerves are lacerated as they pass through the bone, or may even be torn from the bulb (*see* NOSE, Diseases of). The bulb, or tract, may also suffer in adjacent disease, as tumour, abscess, caries of the bone, and meningeal changes, especially syphilitic. Spontaneous atrophy of the olfactory bulbs occasionally occurs in old age, and has been met with in younger persons, and (rarely) in *tabes dorsalis*. Excessive stimulation of the nerve by a very powerful odour has been followed by anosmia.

(c) In *cerebral disease* the sense of smell is sometimes lost. It may be impaired in so-called functional disease, as in hysteria, and in degenerative disease, as paralytic dementia. It is occasionally lost in organic disease involving the roots of the olfactory nerve. Unilateral anosmia has been met with in cases of aphasia (Hughlings Jackson), an association which is explained by the passage of the external root of the olfactory nerve past the island of Reil to the anterior part of the temporo-sphenoidal lobe. Together with the other special senses, loss of smell has been observed on the side opposite to a lesion near the posterior extremity of the internal capsule in the opposite hemisphere.

It is to be remembered that the olfactory nerves are sometimes congenitally absent.

SYMPTOMS.—The evidence of anosmia is the loss of the perception of odours and flavours—the former term being applied to the sensation when its cause enters by the anterior nares, the latter when it enters by the posterior nares and the sensation is blended with that of taste. It is generally imagined that flavours are tasted, and hence those who are suffer-

ing from anosmia are said to have lost smell and taste. The loss of the olfactory sensation may be partial or complete, according to the extent of involvement of the nerves. In some cases, especially of traumatic origin, the ability to perceive one or two odours may be unimpaired, no others being recognised. It may be lost on both sides, when due to degenerative changes; or on one side only, from local changes or injury or brain-disease. When due to organic brain-disease, it is generally lost on the side of the cerebral lesion. Unilateral loss, in hysterical hemianæsthesia, occurs on the side opposite to the hemisphere which is in a state of partial inhibition; and a similar loss, with that of the other special senses, has been met with in rare cases of organic disease.

DIAGNOSIS.—The diagnosis presents little difficulty. In examination, care must be taken to employ only substances—as aromatic oils, &c.—which affect the olfactory nerve, and not acrid substances, as ammonia and acetic acid, which stimulate also the fifth nerve.

PROGNOSIS.—The prognosis in anosmia is favourable when it is due to a local cause which has existed but a short time, or in which its cause (such as obstruction from polypus) can be removed. Prolonged changes in the mucous membrane of the nose seldom pass away sufficiently to permit restoration of smell; and whenever there is reason to suspect injury or disease of the olfactory nerve or centre, recovery is very improbable. Hence traumatic loss of smell, which has continued for some months, will certainly persist.

TREATMENT.—Anosmia, as a symptom, rarely calls for treatment, which should be directed to its cause. Sometimes local stimulation is of service; and occasionally counter-irritation, by blisters to the neck, has appeared to assist recovery. In hysterical cases faradisation of the nasal mucous membrane has been recommended; but the olfactory nerve itself is not accessible to electrical stimulation. The chief therapeutical measures are those for the treatment of the nasal mucous membrane. *See* NOSE, Diseases of.

W. R. GOWERS.

OLIGÆMIA (ὀλίγος, small; and αἷμα, blood).—Deficiency of the total amount of blood in the body. *See* BLOOD, Morbid Conditions of.

OMENTUM, Diseases of.—*See* PERITONEUM, Diseases of.

ONANISM (Onan).—A synonym for masturbation. *See* MASTURBATION.

ONYCHAUXIS (ὄνυξ, a nail; and αὐξάνω, to increase).—Hypertrophy of the substance of the nails. *See* NAILS, Diseases of.

ONYCHIA (ὄνυξ, the nail).—An inflammatory affection of the matrix of the nail. *See* NAILS, Diseases of.

ONYCHOGRYPHOSIS (ὄνυξ, the nail; and γρυπός, curved).—Curvature or deformity of the nails. *See* NAILS, Diseases of.

ONYCHOMYCOSIS (ὄνυξ, the nail; and μύκης, a fungus).—Parasitic disease of the nails. *See* NAILS, Diseases of.

ONYX.—A collection of pus at the bottom of the anterior chamber of the eye. *See* EYE, Diseases of (p. 505).

OPHTHALMIA (ὀφθαλμός, the eye).—**SYNON.** : Fr. *Ophthalmie*; Ger. *Ophthalmia*.—A term restricted by custom to inflammation originating in the superficial structures of the eye, such as the varieties of conjunctivitis, or the phlyctenulæ which sometimes appear upon the cornea and may give rise to shallow ulcers. See EYE, Diseases of.

OPHTHALMITIS (ὀφθαλμίτις, the eye).—**SYNON.** : Panophthalmitis; Fr. *Ophthalmite*; Ger. *Augenentzündung*.—A term which has been used to express inflammation affecting the whole of the structures of the eyeball. See EYE, Diseases of.

OPHTHALMOMALACIA (ὀφθαλμός, eye; μαλακία, softness).—A term recently applied to a diminution of ocular tension appearing spontaneously. The aetiology of the condition is unknown, though there may be a history of traumatism. Neuralgic pains, dilatation of the pupil, and photophobia may co-exist.

OPHTHALMOSCOPE (ὀφθαλμός, the eye; and σκοπέω, I examine).—**SYNON.** : Fr. *Ophthalmoscope*; Ger. *Augenspiegel*.

The ophthalmoscope is an instrument for lighting up the interior of the eye in such a manner as to render the contained structures clearly visible.

DESCRIPTION.—The first ophthalmoscope was invented about 1847, by the late Mr. Charles Babbage, who laid it aside because an ophthalmic surgeon to whom he showed it, and who failed to perceive its probable utility, afforded him no encouragement. In 1851 another form of the instrument was invented by Helmholtz; but, in 1852, Babbage's original form was re-invented by Ruete, and this, with a few unimportant modifications, has ever since held its ground in practice. It consists, essentially, of a slightly concave mirror, with a small central perforation; or, if the mirror be of silvered glass, with the silvering removed from a small circle in the centre. A mirror the size of a shilling is large enough for most practical purposes, and a central aperture of not more than 2 or 3 millimetres in diameter is better than a larger one. The mirror may be attached to a handle of any proportions preferred by the owner, or may be left without one; but it must be accompanied by certain auxiliary convex and concave lenses, the uses of which will be presently explained. The focal length of the mirror is usually about eight inches.

METHOD OF USE.—In order to learn the use of the ophthalmoscope, the beginner will do well to avail himself of a contrivance called Perrin's artificial eye, or of one of the more elaborate forms of it designed by Landolt and by Frost. The instrument essentially consists of a small hollow sphere of metal, to represent the eye, closed in front by a lens, which can be changed at pleasure, and behind by a door for the insertion of pictures of various healthy and diseased conditions of the retina. When an artificial eye is not available, the learner should take the patient into an obscurely lighted room, and should stand or sit facing him, with the two heads upon the same level. A gas- or oil-flame—preferably, from its greater steadiness and superior illumination, that of an argand burner—is then placed upon the same level as the eye which is to be examined, on the same side of the head, and a little behind it, so that no direct light shall fall upon

the cornea. The observer, commencing with his face exactly opposite that of the patient, and about eighteen inches distant from it, places the back of the ophthalmoscopic mirror against his eye, using preferably that which is opposite to the eye to be examined, the right eye for the patient's left, and *vice versa*. The patient is directed to look as if at a distant object, over the shoulder of the observer which is most remote from the eye under inspection, thus looking over the observer's right shoulder when the right eye is being examined. In this position the observed eye is turned a little towards the nose; and the optic nerve-entrance, which is somewhat on the nasal side of the posterior pole, is brought opposite the pupil. Looking through the mirror-aperture, the observer directs the light of the flame, reflected from the polished surface, in such a manner that it falls into the pupil of the observed eye; and this light, returning from the eye, reaches him through the perforation. It exhibits the cavity of the eye illuminated, but, as a rule, shows no objects, but only the pupil as a reddish or yellowish circle. In order to see the contained structures, two methods are employed, the *indirect* and the *direct*; the former of which gives the better general view of the fundus, the latter the greater facilities for studying the condition of single points on the nerve or on the retinal surface. It is therefore necessary to be conversant with both, and to use one or both as circumstances may require.

Indirect Method.—In using the indirect method, the observer takes a biconvex lens, of about two inches focal length, and holds it with his free hand in the track of the returning light, and at about two inches from the eye of the patient. The rays of light, thus rendered convergent, become united into an aerial inverted image of the fundus of the eye, which image, and not the fundus itself, will be the object of vision to the observer. The position of the image is in the focal plane of the lens, on the side next the spectator; and, in order to see it clearly, nothing is necessary but to have the observing eye in the track of the returning rays, and at the right distance from the image; which, it must be remembered, with a two-inch lens, will be four inches or more nearer to the observer than the eye of the patient. The whole art of using the ophthalmoscope for the indirect method may be said to consist in moving the eye to and fro upon the line of sight until the right distance is attained, without moving it laterally so as to get out of the track of the rays, and without losing the illumination. As soon as a vessel, or any other defined object, is seen, the observer knows that his distance is correct, and he then causes the patient to change the direction of his eye until every part of its fundus has come successively into view. The image, it must be remembered, is inverted in every particular; its nasal side representing the temporal side of the retina, and its upper portion the lower portion of the retina. In first attempts to use the ophthalmoscope it is desirable to have the pupil of the observed eye dilated by atropine or duboisine, but, after dexterity has been attained, the dilatation may in most cases be omitted. The details of the retinal image are sometimes more or less obscured by an image or images of the lamp-flame; of which there may be two, one formed by the anterior and one by the posterior surface of the lens. These images are only sources of embarrassment when the lens is held vertically, and may be displaced and put out of

sight by giving it a small degree of obliquity. A bright image of the mirror itself upon the cornea, showing the central perforation as a dark spot, is sometimes troublesome to beginners; and it is said that this image has even been mistaken for that of the optic nerve. The blackness and sharp definition of the perforation should render such a mistake impossible; and the image may readily be displaced by a slight alteration of the angle at which the mirror is held.

In order to magnify the inverted image, and to increase its brightness by bringing the mirror nearer to the eye of the patient, a convex lens may be placed behind the mirror for the observer to look through. Something of this kind is always necessary for observers who have reached the period of life at which spectacles are required for reading; and it is advantageous to all persons. The writer's practice is to use a lens of about seven inches focal length in this manner; and there is thus obtained an image which for many purposes is as good as that afforded by the direct method. With such a lens the eye of the observer can be only seven inches from the image, and, as this will be formed four inches in front of the eye of the patient, it follows that the two faces will be only eleven inches apart. At this comparatively small distance, the illumination of the fundus of the observed eye, which is afforded by a good mirror, is exceedingly satisfactory.

Direct Method.—In the direct method, the observer does not apply any intervening glass between the mirror and the eye of the patient, but comes as close to the latter as possible, and looks, not at an aerial optical image, but at the actual fundus itself, magnified by its own crystalline lens. It is only when the eyes of both observer and patient are of normal refraction, or emmetropic, that this can be done without the aid of a lens, which when required is most conveniently placed behind the mirror. The lens employed for this purpose must be such as to correct the sum of the error of refraction of both the eyes; and must therefore be concave when this error is on the side of myopia, convex when it is on the side of hypermetropia. An observer who is short-sighted will begin his investigation with a concave lens behind his mirror, which corrects his own short sight; and he will add to or diminish the power of this lens to meet any degree of ametropia which the observed eye may present in addition to, or in diminution of, his own. In order to facilitate the required changes, all necessary lenses are now usually mounted upon a revolving disc placed behind the mirror, and so arranged that each one of them can be brought in turn before the aperture. In one of the best of the modern forms of instrument, that of Loring of New York, the mirror itself is made to turn upon pivots in a vertical line independently of the disc of lenses, so that the correcting lens receives no obliquity from the position of the mirror. This contrivance is valuable in some cases, especially when a correcting lens of high power is required, because such a lens, if held obliquely, is liable to produce some distortion of the objects seen through it. In using the revolving disc, a normal-sighted observer commences with no lens behind the aperture; and, if he then obtains clear definition, he knows that the eye into which he is looking is normal-sighted also, or at most is only in a slight degree hypermetropic. If, on the contrary, he does not obtain a clear image, he knows

that the eye into which he is looking, unless the transparency of its media be impaired, is not normal-sighted, but that it is either myopic, or hypermetropic in a somewhat high degree. Keeping the fundus in view, he causes the disc to revolve until a lens comes over the aperture which renders the picture distinct; and he has then only to see the number and kind of the lens in order to know the degree as well as the nature of the defect of refraction. In many cases it is even possible to prescribe spectacles, as the result of such an examination, with a very fair degree of correctness and success. But the chief use of the direct method, especially in the applications of the ophthalmoscope as an instrument of diagnosis in general medicine, is to scrutinise, as already stated, some portion of the fundus of the eye which has been shown, by the indirect method, to require more minute examination than that method will itself permit the observer to accomplish.

OPHTHALMOSCOPIC APPEARANCES.—In order to interpret ophthalmoscopic appearances, and to distinguish physiological variations from pathological changes, it is before all things necessary to bear in mind the anatomy of the structures which are, or may be, rendered visible, and the relations which they bear to each other. The fundus of the eye is composed of several layers, the more anterior of which commonly conceal the posterior; and conceal them in such a manner that, when the former are rendered more transparent by malformation or disease, the latter are brought into view.

1. *Sclerotic.*—Commencing with the posterior layer, it consists of the inner surface of the sclerotic, a smooth and shining white surface, which is ordinarily entirely concealed by the pigmentation of the choroid and of the posterior or epithelial layer of the retina. The sclerotic is naturally visible, as a general white background to a vascular network, in cases of albinism, in which the natural pigment of the eye is congenitally absent, or in some very fair persons, who are not albinos, but whose eyes are very sparingly pigmented. It is rendered visible in patches, as a result of malformation or disease, in cases in which it is exposed by a fissure through the choroid, such as generally accompanies *coloboma iridis*; in cases in which the choroid has suffered atrophy as a result of antecedent hæmorrhage or inflammation; and in the immediate neighbourhood of the optic discs, in the so-called crescents of choroidal atrophy which are so often associated with high degrees of myopia. The whiteness of an exposed sclerotic may be distinguished from that of an opaque white deposit in the choroid or in the retina, by many small physical characters, such as the relation of the borders of the whiteness to the neighbouring tissues and vessels, which will show the one to be the result of the removal, the other of the addition, of material. The most conspicuous white deposits are those associated with albuminuria or diabetes mellitus, with syphilitic retinitis, and with the first stages of retinal glioma. In all these the deposits manifestly cover and conceal vessels, which may be seen to emerge from beneath them; while in complete atrophy of portions of choroid, it is not uncommon to see a few remains of dwindled vessels, and other shreds of choroidal tissue, rendered unusually conspicuous by their white background, and manifestly situated in a plane anterior to it.

2. *Choroid.*—The next layer from behind forwards is the choroid, which is essentially a vascular

network, containing more or less pigment in the intervals between the vessels. In very fair eyes, as already mentioned, the choroid may allow the general whiteness of the sclerotic to shine through; but, in the great majority of cases, it conceals the latter entirely. In like manner, the actual structure of the choroid is itself usually concealed by the pigment in the epithelial layer of the retina; and the choroid generally only plays the part of a red background, varying up to dark chocolate colour in very dark eyes, and exhibiting neither structure nor vessels. When the retinal epithelium is scantily pigmented, as occurs in light eyes, the larger choroidal vessels may be seen through the retina; and they are readily distinguished from those proper to this structure by their different arrangement; the vessels of the retina being arborescent, while those of the choroid are either nearly parallel to one another, or arranged in more or less diamond-shaped reticulations. When both sets are visible together, moreover, the vessels of the retina will be clearly seen to be in a plane anterior to that of the vessels of the choroid, and a variety of minute differences of colour and aspect will suffice to show that the two sets form parts of different circulatory systems.

3. *Retina*.—The retina itself is formed of several layers, the deepest of which contains the perceptive elements, or the rods and cones of the so-called Jacob's membrane. In front of the perceptive elements there are ganglionic and granular layers, subservient to the functions or to the nutrition of the rods and cones; and, in front of these again, a layer of connective tissue, containing and supporting the conducting fibres, which are ultimately massed together in the trunk of the optic nerve, and which convey impressions from the retina to the brain. The fibre-layer and its connective tissue are necessarily thickest in the immediate neighbourhood of the optic nerve, and they thin off towards the peripheral parts of the retina; while all but the perceptive elements are wholly wanting over a small circle or depression at the posterior axis of the eyeball, a little to the outer side of the nerve, and known as the 'yellow spot,' with its *fovea centralis*. The central artery of the retina enters the eye in the trunk of the optic nerve, and the central vein emerges in the same manner, the circulation between the two being almost a closed one, save for a few very small and insignificant anastomoses of the terminal vessels, some at the nerve-entrance itself, others in the ciliary region. The retinal blood-vessels are chiefly lodged in the connective tissue of the fibre layer, and only small twigs dip down into the deeper retinal tissues. The arteries and arterioles divide, and the veinlets and veins unite, in an arborescent fashion; and the two sets of vessels are readily distinguished apart by the larger calibre and deeper colour of those which carry venous blood. At the nerve-entrance, both sets bend at a right angle, or nearly so, in order to pass from the axis of the nerve-trunk into the plane of the retina, or *vice versa*.

Between the rods and cones of Jacob's membrane, and the anterior or capillary layer of the choroid, there is a sheet of pavement-epithelium, the cells of which contain a larger or smaller quantity of pigment. This epithelial layer was at one time regarded as part of the choroid, but more recent histologists refer it to the retina. When full of pigment, it forms an opaque screen, by

which the choroid is concealed from view, and against which the delicate retinal structures, especially near the nerve, may become apparent as a thin, almost pellucid, film, in which blood-vessels ramify. In the eyes of fair people, with only scanty pigmentation, the epithelium neither completely conceals the choroid, nor does it throw up the retina with anything like the same distinctness, so that the retinal blood-vessels are clearly seen, but not the structure which supports them. When the pavement-epithelium has been removed, either by disease or by senile changes, the choroidal tissues become conspicuous.

4. *Optic Nerve*.—The general aspect of the optic nerve varies greatly, within limits defined by differences in the degree of its capillary vascularity, by the effects of contrast arising from the degree of pigmentation of the surrounding parts, and by the mechanical arrangement of the structures of which it is composed. The aperture in the sclerotic, by which the nerve enters the eye, is closed by a cribriform plate of condensed connective tissue, the *lamina cribrosa*; and the fibres normally leave their sheaths on the outer side of this lamina, only the axis-cylinders passing through its perforations. The combined axis-cylinders constitute a mass; the whiteness of which is subdued rather than glistening, and which derives a certain amount of reddish, roseate, or pink colour from the capillary vessels by which it is permeated. The axis-cylinders, like the vessels, bend round as they pass from their original direction into that of the retinal surface; and, in the majority of instances, they leave a central depression in the nerve-disc as they separate, a depression at the bottom of which the glistening whiteness of the *lamina cribrosa* is visible, and which has been called the *porus opticus*. In other instances, this central depression does not exist, but the axis-cylinders are gathered chiefly towards one side of the nerve-entrance, and the lamina is visible laterally instead of centrally. The size of the *porus opticus* is very variable, inasmuch that sometimes, when it constitutes quite a large central depression, it is described as congenital or physiological excavation of the nerve. This congenital excavation is always readily distinguishable from the excavation produced by the pressure consequent upon excess of internal tension; because the former never, and the latter always, extends to the extreme margin of the nerve. In other words, the congenital excavation, however large and remarkable, is always surrounded by a ring of nerve-tissue; while the morbid excavation always extends to the margin of the opening in the sclerotic. The position of the blood-vessels in the nerve-entrance is also another variable factor, since they are sometimes nearly central, and at others are seen to pass into or out of the nerve-tissue close to its margin. In a few cases, moreover, the axis-cylinders at some portion or portions of the circumference carry their sheaths for a short distance into the retina; and the nerve is then surrounded by white glistening processes, with brush-like terminations. Sometimes, again, the margin of the opening in the choroid is richly pigmented, and the nerve is surrounded with a ring, or bordered by a crescent, of chocolate or black colour.

5. *Fundus as a Whole*.—The general appearance of the healthy fundus oculi may be summed up somewhat in the following way: The background seen in the inverted image ranges in colour from an

almost chocolate tint in very dark people or in the dark races, to a closely woven reticulation of vessels carrying red blood, and affording indications of the white sclerotic lying behind them. In light eyes, the retina itself is invisible; but in dark eyes its thickest portion appears as a delicate film, which has been compared to moistened tissue-paper, over the portion of the field which immediately surrounds the optic nerve. Except in very light eyes, the vessels of the choroid are not individually visible, being concealed by the pigmentation of the pavement-epithelium; and, when visible, they are distinguishable by their parallel direction, and by the absence of branches. The vessels of the retina are always clearly visible, and may be traced along their numerous arborescent ramifications to twigs of extreme fineness. The arteries are smaller and brighter than the veins, and often present the appearance of a white line running along the axis of the vessel, almost as if it were a translucent red tube, carrying a white fluid. The veins, larger and darker than the arteries, seldom display the white line. The vessels pass off the optic disc on all sides, but make bold curves which carry them clear of the region of the yellow spot. In the close vicinity of the disc, the vessels are sometimes attended by fine white threads, pursuing the same general course with them, which are apparently coarser portions of the connective tissue by which they are sustained. The optic disc, or termination of the optic nerve itself, the most conspicuous object in the ophthalmoscopic image, stands out boldly against its surroundings, and presents a general colour-effect which depends partly upon the richness of its capillary blood-supply, and partly upon the greater or less degree of pigmentation of the tissues around it. Over part of its surface, generally in or near the centre, but sometimes laterally, it displays the whiter colour of the lamina cribrosa, and the mottling of its perforations for the passage of the nerve-fibres. It is often bordered, either entirely or partially, by a line of dark pigment situated at the margin of the choroidal opening; and it often exhibits also a fine white line at its margin, which is the edge of the opening in the sclerotic, seen through the semi-transparent nerve-tissue. The vessels pass over its margin without deviation or change of plane. The apparent size and shape of the disc depend much upon the refraction of the eye. As seen in the inverted image, it appears comparatively small in a myopic eye, and large in a hypermetropic; while, in cases of astigmatism, it is distorted into the appearance of an oval. In the same way, the refraction modifies the apparent actual, but not the relative calibre of the vessels. In the myopic eye the vessels appear of small diameter, and in the hypermetropic they appear of large diameter; so that no conclusions about their actual size can be drawn until the state of refraction has been taken into account. The fact that the veins are relatively larger or smaller than usual, when compared with the arteries, is, of course, not influenced by refraction, except that, in a hypermetropic eye, such a difference would be more conspicuous than in a myopic, by reason of the more magnified image produced by the optical conditions of the media.

6. *Circulation*.—In a general way, the blood-currents in the vessels of the retina are continuous and uninterrupted; but any hindrance to the entrance of blood may be attended by pulsation, first in the veins and subsequently in the arteries. Such

hindrance may arise from disordered action of the heart, as in cases of insufficiency of the aortic valves; from disease of the coats of the arteries; or from increased resistance on the part of the fluids already occupying the cavity of the eyeball. The venous pulse depends upon an arrest of the outflow through the veins by the pressure of the entering arterial current, which, at the acme of the pulse-wave, has force enough to push back the venous current when there is not room enough for both. Hence, in the venous pulse, the vessels empty themselves in a direction from the centre of the disc towards its periphery, and refill in the opposite direction. The ordinary cause of venous pulse is increased tension or fulness within the eyeball, so that it is among the early symptoms of glaucoma; but it is also to be seen in a small proportion of cases in which no excess of tension is to be discovered either by touch or by symptoms, and in which the eyes appear to be healthy. In the arterial pulse, the resistance to the entrance of blood, or rather the disturbance of the balance between the propulsive and the resisting forces, must be considerable; and the course of events is that the arterial current can only make its way into the eye at the acme of the pulse-wave, during which the arteries fill from the centre of the disc to its periphery, to collapse again as soon as the impulse of the systole diminishes. In such a condition, the impediment to the entrance of arterial blood is sufficient to imperil the nutrition of the nerve-tissue; and the writer has seen at least one case of partial nerve-atrophy, attended by arterial pulsation, for which no other cause than excessive arterial tension could be assigned. Arterial pulse is probably always present in advanced stages of glaucoma; but by the time it is produced, the fundus is usually obscured or rendered invisible by other changes. Apart from glaucoma, its most frequent cause is aortic regurgitation; and in this form the eye does not suffer, except together with other parts of the organism.

7. *Optic Neuritis and Atrophy*.—The morbid appearances seen with the ophthalmoscope, and interesting to the physician, are chiefly those which point to the existence of some diathesis, or to the presence of disease in other organs. Swelling of the intra-ocular extremity of the optic nerve, with obliteration of its margins and obstruction to its vessels, occurs in many forms of intracranial disease, especially in connection with intracranial tumour, and is often followed by atrophy and blindness when life is sufficiently prolonged. The most interesting characteristic of these cases is that, since the swelling affects only the connective-tissue layer, which is absent over the region of the yellow spot, there is commonly no diminution of the acuteness of central vision until the atrophic changes have commenced; by which time, in many instances, the primary swelling has passed away. Hence, for many years, there existed great uncertainty about the cause of the atrophy, and this uncertainty was only removed when physicians began to examine the fundus oculi in all cerebral cases, without regard to the state of sight. Prior to that time, the intra-ocular changes were apt to remain undiscovered in their primary stage, and until commencing impairment of vision produced resort to an ophthalmologist, followed by an ophthalmoscopic examination in due course; and then the atrophy was often attributed to many fanciful causes, among which the smoking of tobacco held a prominent

place. It is not necessary to assume that tobacco is never injurious to the optic nerves, in order to be quite sure that the majority of the instances of atrophy once attributed to its influence were, in reality, due to a totally different cause. The changes associated with intracranial diseases will be found described in a special article. See OPHTHALMOSCOPE IN MEDICINE.

8. '*Albuminuric Retinitis*.'—Very frequently in albuminuria, and occasionally in diabetes mellitus, the fundus of the eye becomes studded over with spots or patches of a glistening white colour, which are probably due to fatty degeneration of the connective tissue of the retina, and which are often associated with scattered hæmorrhages. The blood, in these instances, is usually effused into the fibre-layer, and, following the course of the fibres, becomes spread out into somewhat striated spots, with brush-like terminations. Every case in which either the white patches or the hæmorrhages, or both, are detected by the ophthalmoscope, whether with or without impairment of sight, calls for a careful examination of the urine, and renders it proper to follow mainly the indications of treatment which such an examination may afford. See PLATE IX., fig. 1.

9. *Hæmorrhages*.—Without the white patches, hæmorrhages may occur in the retina under various conditions. Sometimes they are distinctly arterial, in which case they are generally small in absolute amount, and may often be traced to some manifest point of rupture in the vessel from which they have occurred. These hæmorrhages seldom produce extreme impairment of vision, although they are usually discovered on account of some degree of impairment; and their chief importance is derived from the warning they may give of a state of brittleness of the arteries, and of a consequent liability to similar bleedings elsewhere, as in the brain. They call for all the precautions which such a state would suggest, as for the consumption of a diminished quantity of fluid, and for the avoidance of constipation and of all violent bodily efforts.

Hæmorrhages which are distinctly venous occur not infrequently in connection with the disturbances of circulation which are incidental to the cessation of the menstrual function, or to the irregularities by which cessation is preceded. The blood may proceed from comparatively large veins, in which case it often forms a layer immediately beneath the mem-

brana limitans of the retina, causing great temporary impairment of sight, or even total blindness; and yet, in many cases, being quickly absorbed without permanent injury. In other instances it may proceed from smaller and deep-lying veinlets, in which case the effusion will usually be situated in the fibre-layer, and will be moulded, so to speak, by the fibres, into what have been described as 'flame-shaped' hæmorrhages (p. 56). These are generally multiple, and usually cause an impairment of function, which is decided although not total, and is often permanent. The flame-shaped hæmorrhages are said by Hutchinson to occur most frequently in persons of gouty diathesis, and he holds the same doctrine with regard to a less common form, of which some remarkable examples have been observed by himself, and by Eales of Birmingham. In these cases, the subjects were young males, of constipated habit, and in many instances of gouty family history. The bleedings were large in amount, so as to penetrate into the vitreous body and to cause for a time total loss of sight, and were frequently recurrent. To what extent they were due to deficient plasticity of the blood, to abnormal friability of the vessels, to variations in vaso-motor tension, or to the withdrawal of external support from the vessels by diminished tension within the eyeball itself, is at present a matter of conjecture. It is obvious that the treatment of such cases, and of retinal hæmorrhages generally, must resolve itself into that of the constitutional conditions with which they are associated. The only special indications, as regards the eye, will be the enforcement of functional rest, and the maintenance of an elevated position of the head during sleep. In cases connected with the cessation of the menstrual function, the absorption of the effused blood often appears to be promoted by the careful administration of iodide of potassium, which should usually be combined with ammonio-citrate of iron, or with some other suitable tonic, and care should always be taken to maintain a moderately relaxed condition of the bowels. Even apart from the injurious effects likely to be produced by straining, constipation appears to predispose to hæmorrhage.

10. *Embolism of the Central Artery*.—Sudden loss of vision is sometimes occasioned by the plugging of the central retinal artery by an embolus. This is especially to be suspected in cases of known valvular disease of the heart, and the condition is

FIRST PLATE (DIVIDED INTO SIX).

1. *Normal Optic Disc*. The edge is distinct all round. To the outer side of the entrance of the central vessels is a roundish pale area (physiological pit) with a dotted appearance on its floor (lamina cribrosa). Left eye: erect image.

2. *Slight Optic Neuritis*. The edge of the disc is concealed above, and down and in; it is visible, but blurred, elsewhere. The physiological pit is indistinct. Veins somewhat distended. Outside the disc are several retinal hæmorrhages (round and punctate). The drawing is from a case of renal disease, and the degenerated arteries are shown to indent the underlying veins where they cross over them. Left eye: erect image.

3. *Gross Optic Neuritis*. The edge of the disc is quite invisible everywhere. The disc is evidently raised above the level of the adjacent retina, as is indicated by the curve of the vessels. The colour of the nerve is changed, being redder than normal, particularly at its periphery, where numerous red streaks radiate outwards (dilated small vessels lying between the nerve-fibre bundles). The physiological pit is filled in by opaque inflammatory exudation and swollen nerve-fibres, and this opaque material also obscures the arteries in places. The veins are distended and very tortuous. From a case of cerebral tumour. Right eye: erect image.

4. *Optic Neuritis in stage of subsidence, with commencing Atrophy*. The edge of the disc is still concealed except outwards, where it is just beginning to come again into view. In general colour the disc is markedly paler than normal, with some opaque tissue (organised exudation) filling up the physiological pit and obscuring the central vessels at their entrance. The veins are still darker than normal and tortuous. Right eye: erect image.

5. *Optic Atrophy consecutive to Neuritis*. There is still a little blurring of the edges above and below, which will probably disappear later. Elsewhere the edge is distinct, and shows pigmentary change in the adjacent retina. The disc is white almost everywhere, and the lamina cribrosa is concealed. The retinal arteries are becoming reduced in calibre: the veins will also later become smaller. Left eye: inverted image.

6. *Simple Optic Atrophy*. The edge of the disc is sharply defined. In colour, the disc is pale bluish-grey, with distinct white physiological pit. The stippled appearance of the lamina cribrosa is visible over a large area. The central vessels are somewhat reduced in calibre, and the veins show no trace of any increased tortuosity. Left eye: erect image.

5.

6.

Commonly bilateral, it is in rare cases unilateral, and is then more common in the eye opposite to the seat of the tumour. It may exist in considerable degree without impairing sight. Perception of colour is affected before acuity of vision. If the tumour be arrested by treatment, as in syphilitic and tubercular growths, the neuritis will subside; it also often lessens when the intracranial pressure (which drives the fluid into the sheath of the nerve) is lessened by trephining the skull, and, still more completely, after removal of the tumour, when this can be effected. Too often, however, before this result is obtained, sight has been damaged beyond recovery. Secondary atrophy of the optic nerves sometimes results from tumours in the neighbourhood of the chiasma, although far less commonly than 'consecutive atrophy.' See also p. 198.

Intracranial aneurysms are rarely accompanied by intra-ocular changes. Now and then, an aneurysm of the internal carotid has caused atrophy by pressure, and even optic neuritis, single or double.

Internal hydrocephalus is usually accompanied by no other ophthalmoscopic changes than slight fullness of the veins. Occasionally simple atrophy occurs, commonly from the pressure of the distended third ventricle on the optic commissure.

Meninges.—Growths in the meninges lead to optic neuritis, just as do tumours in the cerebral substance. The effect of meningitis varies according to its form and seat. Simple meningitis of the convexity is rarely attended by ocular changes. It is very different with basal tubercular meningitis. Occasionally, though rarely, tubercles of the choroid may be seen. In a considerable number of cases there is distinct neuritis; it is well-marked in at least half. Usually too late to be of diagnostic importance, it is now and then sufficiently early to decide the nature of the case. A similar change is common in both syphilitic and traumatic meningitis, but is rare in the epidemic cerebrospinal form, except in cases of unusual duration.

Diseases of the cranial bones.—Caries of the sphenoid bone may cause descending neuritis; caries elsewhere usually only affects the eye by causing meningitis or abscess. Thickening of the cranial bones may be attended by neuritis, but usually the first visible result is atrophy. This is apparently produced by the resulting constriction of the nerve and sheath at the optic foramen. Distension of the sphenoidal sinuses may damage one or both nerves by pressure on them as they pass through the optic canals; in this affection the nasal part of the nerve is first involved. Inflammatory mischief or growths in the orbit frequently cause neuritis or atrophy, the optic nerve-trunk being damaged directly. In these cases the affection is

unilateral, at least for a long time, and is often accompanied by prominence of the eyeball, and tenderness when it is pushed back.

Injuries to the head may affect the eye in various ways: (1) The retina may suffer in consequence of the immediate concussion. (2) Optic neuritis may come on after a few days, commonly as the result of a traumatic meningitis. (3) Direct injury to the optic nerves may cause loss of sight and simple atrophy. (4) Optic neuritis may come on some weeks after the injury, and is usually due to inflammatory processes in the damaged brain.

2. Spinal Cord.—*Acute myelitis and spinal meningitis* are very rarely attended by eye-changes. In one or two cases coincident optic neuritis has been observed. The connection between the two is obscure; probably they are independent effects of a common cause, e.g. a blood-state. *Sclerosis of the posterior columns* (locomotor ataxy) is accompanied by atrophy of the optic nerves in a considerable number of cases, although not perhaps in more than 15 per cent. When it does occur it is frequently an early rather than a late symptom. It is always the simple form of atrophy, often grey, with unnarrowed vessels. Sight usually suffers gravely; the field of vision is much restricted; and perception of colours may be lost. The atrophy is not the result of any extension upwards of the disease in the posterior columns. It may occur when this has scarcely commenced, and even years before the earliest symptoms. It is apparently an associated degeneration. In *lateral sclerosis* changes in the fundus oculi are, as a rule, absent. In *disseminated sclerosis*, optic nerve-atrophy may occur, just as in posterior sclerosis, but less frequently. Damage to sight, without marked ophthalmoscopic changes, occasionally results from the sclerosis invading the optic commissure or nerves. In caries of the spine, changes in the optic disc are practically unknown. In very rare cases of injury to the spine, neuritis and subsequent atrophy have been observed, but these results are so uncommon that their precise significance is doubtful.

3. Functional Diseases.—In *exophthalmic goitre* the only ophthalmoscopic change is increased size of the retinal arteries, which may pulsate visibly. In *chorea*, embolism of the central artery of the retina has been once or twice observed; and optic neuritis, slight in degree, is not unknown. It is usually met with in hypermetropic eyes, but, nevertheless, subsides when the chorea is over. With *neuralgia* of the fifth, optic nerve-atrophy has been observed; the nature of the association is doubtful. In *idiopathic epilepsy* the appearance of the fundus is, as a rule, perfectly normal. Even during an attack it is probable that the only change is distension of the veins in the stage of cyanosis. But

SECOND PLATE

(DIVIDED INTO TWO).

1. Retinitis in Renal Disease. The edges of the disc are hazy, from œdema. There are numerous retinal hæmorrhages, chiefly of striated form near the disc. White fluffy opacities are present in the inner layers of the retina, obscuring the vessels in some places: these were unusually numerous and marked in this particular case. The arteries are rather narrow and show irregularities in calibre, particularly the large branch passing downwards and outwards; they indent the veins where they cross over them. At the macula there is an incomplete stellate figure, formed by white lines and streaks radiating from the fovea centralis: these lines are usually, as here, best marked between the fovea and the disc. Right eye: erect image.

2. Disseminated Choroidal Atrophy in inherited Syphilis. Round or oval patches are seen distributed over the fundus. Each spot or patch has a punched-out appearance, the centre being light in colour and evidently on a deeper level than the adjoining healthy retina. This centre is usually surrounded by a deeply pigmented black border, outside which again there is a pale zone. The retinal vessels pass uninterruptedly over any patch that may chance to underlie them. The disc is paler than normal and has an opaque dead look. In this case the retinal vessels are not decidedly abnormal, but frequently in such cases they are much reduced in size, particularly the arteries. Right eye: erect image.

Our thanks are due to Messrs. Nettleship, Lawford and Spicer for the loan of original drawings from which several of these illustrations have been taken.—R. M. G.

1.

2.

during the status epilepticus, when attacks recur with great severity for several days, a condition of slight neuritis may be produced, subsiding after the attacks are over. In cases of *convulsions* from organic brain-disease, it must be remembered, optic neuritis or its effects are often met with. The frequency with which morbid appearances are to be seen in the eye in *insanity* has been variously stated, and by some writers unquestionably exaggerated. They are most frequent in general paralysis of the insane. Optic nerve-atrophy is the usual change, and is sometimes an early event, just as in locomotor ataxy. In very rare cases slight neuritis has been seen. In mania, melancholia, and dementia it is probable that there are no related morbid appearances in the eye.

II. DISEASES AFFECTING THE URINARY SYSTEM.—1. **Bright's Disease.**—Sight may be impaired in this complaint by uræmic poisoning, or by retinal changes. The latter may occur, even in considerable degree, without any affection of vision. The arteries may occasionally be conspicuously narrow (contracted), and in rare cases may present sclerosis of the outer coat, or minute aneurysms. Aneurysmal dilatations of the capillaries may often be found *post mortem*, in association with other degenerations, and probably sometimes constitute one cause of the occurrence of a very common change in the retina—hæmorrhages. These are usually striated, situated in the nerve-fibre layer; sometimes they are irregular in shape, and situated in the deeper layers. They may detach the retina from the choroid, or burst through into the vitreous. Sometimes they exist alone; more commonly they are conjoined with other changes, to which the term 'albuminuric retinitis' is given. This latter change may occur in all forms of renal disease, but is by far the most common in the granular kidney. It is a late symptom, never appearing until the general system is suffering. The disease of the retina presents certain elements which are variously combined in different cases. (1) Diffuse slight opacity and swelling of the retina, due to the infiltration of its substance by an albuminous coagulable liquid (œdema). (2) White spots and patches of various size and distribution: some large and soft-edged; others minute, and of pearly whiteness. They are due to fatty degeneration of the retinal elements, or to granular degeneration of albuminous exudations. The small white spots often radiate round the fovea centralis. (3) Hæmorrhages. (4) Inflammation of the optic papilla—'neuritis.' (5) The subsidence of the inflammatory changes may be attended by the signs of atrophy of the optic nerve and retina. According to the predominant character, four types of retinal affection may be distinguished: a degenerative, hæmorrhagic, inflammatory, and neuritic form. In the first the white spots predominate, and there are usually extravasations, but there is little diffuse opacity. In the second the hæmorrhages are so abundant as to be the chief feature. In the third there is much diffuse opacity and swelling of the retina. In the fourth the optic neuritis is in excess of the other changes, and the appearance may easily be ascribed to cerebral disease—the more so that it is often conjoined with headache, and other evidence of cerebral disorder, so that the urine should be carefully examined in all such cases. The conspicuous combination of white spots and hæmorrhages usually enables the retinal affection of albuminuria to be

recognised without difficulty. It may be confounded with the degeneration left by a previous wide neuro-retinitis, but in such cases the signs of atrophy will be conspicuous. The course of the affection in Bright's disease is often progressive, but arrest and even recovery may be obtained by the treatment of the renal disease. When extensive, sight is usually impaired, but is rarely completely lost.

2. **Diabetes Mellitus.**—In diabetes mellitus, in rare cases, retinal changes have been observed, very similar to those of the degenerative form of the albuminuric affection, and this when there was no albumen in the urine. Miliary aneurysms have been found *post mortem*. A distinction from the renal form is the frequency with which there are opacities in the vitreous, due probably to slight extravasations of blood.

III. DISEASES OF THE HEART.—The peculiar conditions of the intra-ocular circulation prevent any dynamical changes in the circulation. Venous distension, if considerable, may be visible in the eye, especially in cyanosis. When arterial pulsation is strong, it may be seen in the retinal arteries, as in aortic regurgitation, and also, it is said, in exophthalmic goitre. Embolism of the central artery of the retina may occur, and, like embolism elsewhere, is most common in mitral constriction. In ulcerative endocarditis, accompanied by multiple embolism, retinal hæmorrhages occur, for the most part round, with a pale or white centre. They are almost pathognomonic.

IV. DISEASES OF THE BLOOD.—Acute *anæmia* from hæmorrhage may be followed by loss of sight, slight or considerable, transient or permanent. The accident most commonly follows hæmatemesis, uterine hæmorrhage, or venesection. In some cases no ophthalmoscopic changes have been found; in others there has been neuro-retinitis. The mechanism of the affection is obscure. Simple chronic *anæmia* is accompanied by marked pallor of the veins, sometimes of the choroid and disc, but the latter is always within the physiological variations in tint. Occasionally in chlorosis optic neuritis is met with, developing quickly to a high degree of intensity, such as is met with in cerebral tumour. It disappears rapidly under iron, but too often ignorance of the cause has led to the loss of so much time, while iodide of potassium, &c., have been given, that sight is hopelessly damaged. In *pernicious anæmia* the choroid is notably pale, the arteries small, the veins very broad (atonic) and pale. Hæmorrhages are frequent, especially around the optic disc, and they are often associated with white patches (p. 56). Some extravasations are rounded, with a white or pale centre. Occasionally there is marked neuritis. In *leucocythæmia* the pallor and the width of the veins are very striking. Extravasations are almost invariable at some period. White spots are frequent, some degenerative, others due to aggregations of leucocytes, some are surrounded by a halo of extravasation. There may also be considerable general swelling of the retina, throwing the distended veins into conspicuous antero-posterior curves. In *purpura* and *scurvy* retinal hæmorrhages also occur. In the intense forms of *purpura*, indeed, they are probably constant, and may be large. They have sometimes been seen in the choroid.

In rare cases of *menstrual* disorders, and still rarer instances of *intestinal* disturbance (chronic diarrhœa), optic neuritis has been observed. Suppression

of the menses has been followed by retinal hæmorrhages. The connection between the several events is obscure.

V. CHRONIC GENERAL DISEASES.—In chronic general diseases ophthalmoscopic changes are met with occasionally. In *tuberculosis*, tubercles may form in the choroid, and be recognisable as small, round, yellowish-white spots, free from pigment. They have more frequently been found in this situation after death than during life, perhaps because not looked for with sufficient perseverance, since they may form rapidly. They are sometimes of great diagnostic importance, especially in cases of general tuberculosis, causing obscure and ill-defined symptoms. In *syphilis* ocular changes are, as is well known, common, but they come chiefly under the care of the surgeon. Traces of past iritis, or of choroiditis—areas of choroidal atrophy with irregular accumulation of pigment—frequently afford the physician important evidence of the previous existence of syphilis, acquired or inherited. In the latter the choroidal changes are of especial importance, and may be confined to small round white spots with pigment in the centre, or there may be evidence of more extensive choroiditis or merely of choroiditic atrophy, a yellowish disc, with the edge a little blurred, and very small retinal vessels. *Gout* has been supposed to cause retinal hæmorrhage (Hutchinson), and to it is probably due the widespread ‘hæmorrhagic retinitis’ that is the consequence of thrombosis in the central vein of the retina. Intra-ocular neuritis is seldom due to this cause, except in slight degree, as the result of a more intense inflammation behind the globe. This may occur in the subjects of acquired gout, or in young persons the subjects of the inherited disease, and may be on one side or on both, simultaneously or in succession.

In *lead-poisoning*, besides the amblyopia which may come on without marked ophthalmoscopic changes, atrophy of the disc is occasionally met with, preceded, in some cases, by a stage of congestion—a red disc, with softened edges, without swelling. A considerable degree of neuritis, double, with swelling and hæmorrhages, occurs occasionally, especially in connection with cerebral symptoms, but without any coarse lesion of the brain. In *chronic alcoholism*, optic-nerve atrophy has been described, and also a condition of congestion. The amblyopia which accompanies the atrophy is said by Förster to be characterised by loss of central vision for colour. The same fact is well established with regard to *tobacco amaurosis*, in which similar congestion and atrophy may occur.

VI. ACUTE GENERAL DISEASES.—In acute general diseases, changes in the fundus are for the most part rare. After *typhus*, *typhoid*, and *scarlet fevers*, optic neuritis has been occasionally observed, apart from any renal or cerebral complication. The renal sequelæ of scarlet fever may of course lead to the special retinal changes. *Malarial fevers*, *ague*, &c., are frequently attended by retinal hæmorrhages (Poncet, S. Mackenzie). Sometimes the extravasations have paler centres. Optic neuritis and atrophy have also been observed. *Erysipelas of the face* has been accompanied by loss of sight, and followed by atrophy, probably by the extension of the inflammation to the orbit, and to the trunk of the optic nerve. *Pyæmia* and *septicæmia* have long been known to be occasionally accompanied by metastatic panophthalmitis, and

recent observation has shown that slighter alterations in the fundus oculi frequently accompany the severer forms of these affections. Of these the most important are retinal hæmorrhages, round or irregular, sometimes large, and often with pale centres, as in ulcerative endocarditis. Although it is probable that they are in some cases due to septic embolism, they may occur without endocarditis, and may be due, in some cases, to chemical changes in the blood, produced by the organised virus of the septicæmia. They are almost invariably in puerperal septicæmia (Litten). They are of very grave significance, but not necessarily a fatal omen. In other cases a peculiar form of retinitis has been observed, with white spots about the papilla and macula lutea (Roth).

R. MARCUS GUNN.

OPISTHOTONOS (ὀπισθεν, backwards; and *τόνος*, a stretching).—A tetanic spasm, in which the body is arched backwards, so that it rests on the head and heels. See TETANUS.

OPIUM, Poisoning by.—In consequence of the extent to which opium and its preparations, including morphine, are used for the relief of pain, and the readiness with which these drugs are procurable, poisoning by these agents is of frequent occurrence; and there is no doubt that great numbers of infants perish every year in this country through the improper use of quack remedies containing opium.

So far as toxicology is concerned, the effects of opium may be referred exclusively to morphine; since the effects of the other active constituents of the drug are overshadowed by those of its chief alkaloid. See also MORPHINE-HABIT, p. 611.

ANATOMICAL CHARACTERS.—The *post-mortem* appearances after opium-poisoning may be almost *nil*. As a rule the brain is congested, the *puncta cruenta* being especially marked; and the lungs and right side of the heart may exhibit an engorgement, as if from a modified asphyxia; but this condition is by no means invariable.

SYMPTOMS.—The first effect of the administration of a toxic dose of opium—a state of *bien-faisance* or exaltation—commonly observed also after the administration of a medicinal dose, may be either very short or entirely wanting; and this is usually the case when morphine is injected hypodermically. A second stage, in which the symptoms closely resemble those of congestion of the brain, soon sets in. The face is either suffused or cyanosed; the pupils strongly contracted; the skin dry and warm; the breathing slow, deep, and becoming stertorous. The patient is apparently unconscious, but may be aroused by shaking, or shouting in the ear; and when he is aroused, the respirations become more rapid, and the skin may regain its normal colour. The symptoms of this second stage may gradually ameliorate under appropriate treatment; or a third stage—that of prostration—supervenes. The coma is now profound, and it may be impossible to arouse the patient. The pupils are contracted to the size of pin-points; or towards the termination of life may be widely dilated. Respiration is now very slow, shallow, with gradually increasing intervals, during which there are no signs of breathing, and the patient lies in a death-like calm. The face is at once pallid and cyanosed; the skin is bathed in

perspiration, at first warm, and then cold and clammy. The pulse increases in rapidity, with progressively increasing feebleness. The patient may even now recover, signs of life returning very gradually; or death may occur from failure of respiration, the other functions of life becoming also gradually extinguished.

Unusual symptoms in opium-poisoning are trismus and convulsions. In children toxic doses may produce very rapid effects, the second stage of the intoxication being wanting, and severe collapse and complete unconsciousness rapidly supervening.

DIAGNOSIS.—The certain diagnosis of opium-poisoning is often a matter of great difficulty, as the symptoms may differ in no material respect from those exhibited in congestion of the brain, however produced, apoplexy, and uræmia. The case may also be confounded with profound alcoholic intoxication. It may also be difficult or impossible to diagnose from poisoning by chloral hydrate—a matter of less importance, since the treatment of the two cases would be similar. The differential diagnosis of opium-poisoning rests upon the equally and minutely contracted state of the pupils, a condition which is all but universal in the second stage of opium-poisoning; our ability to arouse the patient temporarily, the rousing being followed by more or less complete disappearance of the cyanosis of the countenance, and by increased rapidity of respiration; and the profuse warm or clammy cold perspiration. An examination of the urine, which may have to be drawn off by the catheter, for albumen and morphine by the iodic-acid test should always be made; but it must be borne in mind that uræmia and opium-poisoning may be co-existent.

PROGNOSIS.—This is at all times doubtful. There is great liability to relapse, even when the patient appears to be doing well.

TREATMENT.—First, evacuate the stomach by means of the stomach-pump or tube, or, failing this, by the use of emetics. These, however, act with difficulty in cases of opium-poisoning; and there is a special danger in the use of depressing emetics, as, for example, tartar emetic, on account of the possible retention by the stomach of a fatal dose of the emetic. Warm mustard and water, and carbonate of ammonium are the best emetics to administer. The free administration of a dilute solution of potassium permanganate—1 per 1000—is advisable, morphine being destroyed by this agent. A good plan is to wash out the stomach frequently with the above solution. The patient must be prevented from lapsing into a state of somnolence, by walking him about at frequent intervals; alternate warm and cold applications to the chest; flicking the feet with a damp towel; shouting into the ear; and the application of the faradic current; but in severe cases such a procedure cannot be safely adopted. These means will have the additional advantage of maintaining the flagging respiration, and restoring normal breathing. In the last resort artificial respiration must be freely employed. The absorption of the alkaloids of opium may be delayed by the free administration of solutions containing tannin, so as to render the alkaloids insoluble; and among the best media containing tannin are strong infusions of tea and coffee. The caffeine which these infusions contain itself also exerts a powerful remedial influence in this form of intoxication. Atropine, as a respiratory stimulant, appears also to be

serviceable as a direct antidote to morphine. It is best given by subcutaneous injection, in doses of $\frac{1}{40}$ to $\frac{1}{20}$ grain. Hypodermic injections of strychnine may be employed. Alcoholic stimulants should be freely given.

THOMAS STEVENSON.

OPIMUM-HABIT.—See MORPHINE-HABIT, p. 611.

OPTIC NERVE AND TRACT, Diseases of. The optic nerve may be damaged by various intra-ocular processes; but these, and also its primary atrophy, have been already described (*see EYE, AND ITS APPENDAGES, Diseases of; OPHTHALMOSCOPE; and OPHTHALMOSCOPE IN MEDICINE*). In this article only those affections which are situated behind and independent of the eye will be described.

Passing from the orbit into the intracranial cavity by the optic foramina, into which they closely fit, the optic nerves are connected at the chiasma, where an approximate semi-decussation takes place. From the chiasma each optic tract, containing fibres from the same-named halves of both retinae, passes backwards, between the crus cerebri and the inner edge of the temporo-sphenoidal lobe, to the posterior portion of the optic thalamus, where it becomes connected with this and the external geniculate body. Fibres pass also to the corpora quadrigemina, especially the anterior; and from or by the thalamus to the white substance and convolutions of the occipital lobe.

ÆTIOLOGY.—In the orbit the nerve may be damaged by inflammation, which is sometimes apparently due to gout, and sometimes invades the nerve from the orbit (as in orbital cellulitis from facial erysipelas), or is produced by exposure to cold. Inflammation outside the nerve does not always invade its substance on account of the thickness of the sheath which invests it, but the fibres are damaged by the pressure of the inflammatory products. It may also be compressed by an aneurysm of the ophthalmic artery or by orbital tumours; or may be itself the seat of morbid growths or of hæmorrhage. At the optic foramen the nerve may be compressed by new-growths or by a narrowing of the foramen, such as occurs in thickening of the cranial bones, an occasional consequence of syphilis, acquired and congenital. Within the skull, the nerve in front of the chiasma may be damaged by the extension of inflammation from the meninges. The optic commissure is occasionally compressed by or involved in growths, and may be compressed by great distension of the third ventricle. Interstitial inflammation probably sometimes occurs. The nerves in front of the chiasma, and the chiasma itself, are liable to be damaged by the pressure of aneurysms of adjacent arteries. The optic tracts may be involved in hæmorrhage into, or softening of, the crura cerebri; but the most frequent cause of their damage is a tumour arising at the base of the brain, or in the adjacent part of the temporo-sphenoidal lobe. The central continuation of the optic nerves, constituting the visual path—the optic thalamus, the white substance from it to the occipital lobe, and occipital cortex, may be damaged by tumour, softening, or hæmorrhage, with impairment of sight as the result. The corpora quadrigemina are rarely affected so as to cause visual symptoms, except by growths, which produce this effect by pressure on the adjacent visual path to the cortex.

SYMPTOMS.—Damage to the optic nerve, between the optic commissure and the eye, causes an affection of sight in that eye only. There may be either a concentric, a central, or a sectorial defect in the field, or complete blindness; the direct reflex action of the pupil is impaired. When the nerve is slowly compressed, the loss of sight is followed by slow atrophy of the intra-ocular extremity. When it is invaded by inflammation, this usually descends to the eye, and is visible as intra-ocular neuritis, often slight. Inflammation at the back of the orbit usually also involves the motor nerves, and so may cause paralysis of all the ocular muscles. These recover, however, much more readily than does the optic nerve. When the nerve is compressed by narrowing of the optic foramen, the loss of sight is accompanied by intra-ocular atrophy, sometimes preceded by slight neuritis. This is also present in most cases in which inflammation extends from the meninges to the intracranial part of the optic nerves, or the optic chiasma. Damage to the chiasma usually affects the sight of both eyes. In most cases the decussating fibres suffer chiefly or alone, and consequently there is loss of function of the inner half of each retina, and loss of the outer half of each field of vision—*temporal hemianopia*. Damage to the outer part of the commissure on each side affects the fibres which do not decussate, and so causes loss of function of the outer half of each retina, and so loss of the inner half of each field—*nasal hemianopia*. This is very rare, but has been seen from calcification of the carotid artery on each side (Knapp). Partial nasal hemianopia is also sometimes met with in tabes. In irregular damage to the chiasma the loss of vision may be irregularly distributed in the two eyes.

The optic tract receives fibres from the half of each retina on the same side, and its damage thus causes loss of sight in the opposite half of each field of vision—*lateral or homonymous hemianopia*. The loss is often more extensive in the eye on the side opposite to the lesion than in that on the same side. Since the motor tract, in the adjacent crus cerebri and hemisphere, has decussated at the medulla, if it is also involved in the lesion, there is hemiplegia on the same side as the loss in the field of vision. The patient is unable to see to the side on which he cannot move the limbs. Thus the writer has recorded a case in which a patient had, first, right hemianopia, and afterwards right hemiplegia. Both were due to a small tumour of the inner part of the temporo-sphenoidal lobe, which had first invaded the optic tract and then the crus.

Lateral hemianopia results, occasionally, from disease of the posterior extremity of the optic thalamus, and frequently from a lesion involving the fibres that pass thence, adjacent to the posterior extremity of the internal capsule, and through the white substance of the occipital lobe, to the cortex at the extremity of the hemisphere, and chiefly to the lips of the calcarine fissure, disease of which always entails this symptom. Partial disease of this area causes a partial loss of the half field; the upper quadrant is lost if the lower lip of the fissure is diseased, the lower quadrant of the field if it is the upper lip of the fissure. It is uncertain whether damage to the cortex on the outer surface of the occipital lobe causes hemianopia, or whether, with this lesion, the symptom has been due to the disease penetrating the white substance to the fibres from the cuneus. These fibres, the 'optic radiation of

Gratiolet,' may be reached by extensive disease of the middle part of the cortex, and then hemianopia may be associated with hemiplegia, and even with aphasia. When the cause of hemianopia is disease of the chiasma or tract, the pupil does not contract when light is thrown on the blind half of the retina, because the fibres for the reflex centre are involved. When the disease is in the thalamus or occipital lobe there is no loss of action; this affords a means of distinction, but much care is needed to get clear results.

Double hemianopia involves complete loss of sight, and is the probable cause of such loss, when of sudden onset. Half loss of the colour-fields, with no loss for white light, has been observed, and perhaps depends on the existence of a distinct hemiopic colour-centre.

In hysteria, with loss of the other special senses on one side, there is a peculiar affection of vision, which is said to be sometimes met with as a result of organic disease—'crossed amblyopia.' There is dimness of sight of the eye opposite to an organic lesion, and great contraction of the field, with loss of colour-vision; on the side of the lesion there is a much slighter but similar change. It is stated that in the cases in which the lesion has been ascertained, it has always involved the angular gyrus in the postero-inferior angle of the parietal lobe, in front of a line drawn across the brain from the parieto-occipital fissure. It would seem that here there is a centre related to both half-vision centres, in which they are recombined, but to which the opposite field is chiefly related. A partial lesion in this centre can be compensated by the other hemisphere, but the effect of a partial lesion in the half-vision centre is permanent, as much so as one in the optic path leading to it.

Any one of the diseases to which the brain is subject has the same effect if in a corresponding situation; but, as a rule, softening from arterial obstruction, due to syphilitic disease or atheroma, or a new-growth, is a more frequent cause of damage to the optic path in tract or hemisphere than is cerebral hæmorrhage.

DIAGNOSIS.—The chief points which are our guides in determining the position of post-ocular disease, causing loss of sight, have been already stated. If the affection of sight is confined to one eye, it is probably—and if associated with unilateral optic neuritis it is almost certainly—due to disease of the nerve in front of the chiasma. In this case the reaction of the pupil to light is impaired. On the other hand, if the unioocular affection of sight is associated with hemiplegia, and especially with hemianæsthesia, on the same side, it is probable that the disease is in the hemisphere, and the failure of sight is produced in some manner at present unknown. In this case the pupil acts well to light. Lateral hemianopia indicates disease of the tract, the posterior part of the thalamus, or the white substance between the thalamus and the occipital convolutions, or of these convolutions themselves. In which of these positions it is, must be determined by the indications of the localisation of disease of the brain (BRAIN, Tumours of). Nasal hemianopia or temporal hemianopia indicates disease of the optic chiasma.

PROGNOSIS.—This must be influenced by the position of the lesion, and especially by its nature. When there is simple pressure on the optic nerve, sufficient to abolish sight, the prognosis is very un-

favourable. Damage due to the extension of inflammation often lessens considerably. In disease of the optic commissure or optic tracts the prognosis is also grave, because the morbid processes, from which these parts suffer, rarely recede. Whether it is likely to become stationary must be inferred from its probable nature. On the other hand, in disease of the hemisphere, considerable improvement often takes place, just as it does in other symptoms; but when the hemianopia has become stationary it persists, with little change, to the end of life. Often, however, this symptom is thought to have disappeared when it still persists in a diminished degree.

TREATMENT.—The treatment is essentially that of the disease to which the symptom is due, and need not be further discussed in this place.

W. R. GOWERS.

R. MARCUS GUNN.

OPTIC THALAMUS, Lesions of.—See THALAMUS OPTICUS, Lesions of.

ORBIT, Diseases of.—**SYNON.** : Fr. *Maladies de l'Orbite*; Ger. *Krankheiten der Augenhöhle*.—The diseases of the orbit are not numerous, and are almost exclusively surgical in their character. The bony walls of the cavity are liable to be fractured by direct injury, which generally implicates other portions of the skull; the contained tissues are liable to phlegmonous or suppurative inflammation; and the cavity may be the seat of tumours of various kinds, arising either from the walls or from some portion of the contents.

1. **Hæmorrhage.**—Hæmorrhages into the orbit, excepting as results of injury or from the rupture of aneurysmal tumours, are extremely rare; and the few cases which have been recorded have nearly all occurred in persons of generally hæmorrhagic tendency, as one local manifestation among others of a constitutional malady.

2. **Emphysema.**—Emphysema of the orbit is not unknown, and the writer has seen a young man who, in blowing his nose violently, must have ruptured some of the ethmoidal cells, for he distended his left orbit with air, and, in his own words, blew his eye nearly out of his head. The distension soon subsided, and no permanent injury was done.

3. **Inflammation.**—Inflammation of the tissues within the orbit is not a common affection, but it is liable to occur as a complication of fevers and other debilitating diseases, and especially as a complication of erysipelas of the head and face. It is marked by brawny swelling of the eyelids, with some protrusion of the eyeball and some limitation of its movements, the symptoms appearing too suddenly and increasing too quickly to be attributable to the growth of a tumour. The injection of the conjunctiva is generally less marked than that of the lids, and sight is scarcely or not at all impaired so long as the swelling is only moderate in amount. When the injected conjunctiva of the eyeball becomes oedematous, and more especially when the oedema is limited to one sector of the globe, or is much more pronounced over one sector than elsewhere, it is, in the opinion of the writer, an almost pathognomonic sign of supuration; and the localisation of the oedema will serve as a guide to the position in which pus may be looked for. Other symptoms of supura-

tion, such as rigors, must of course be taken into account.

TREATMENT.—As soon as pus is believed to exist, it should be evacuated, since its retention among the orbital tissues may be productive of serious injury, not only to the eye, but also to the ocular muscles and to the nerves which traverse the orbital cavity. The evacuation is usually best effected by introducing a narrow straight knife through the skin, near the margin of the orbit in the selected position, and by thrusting it carefully onward as far as may be prudent, giving the blade an occasional turn upon its axis, to allow of the escape of pus as soon as it is reached. The direction of the point should be governed by complete knowledge of the anatomy of the parts; and it is better to withdraw the blade too soon than to incur any risk of wounding important structures. When it is withdrawn, if no pus follow, the puncture may be carefully deepened or extended laterally by a probe; but it is not necessary to be very strenuous in such endeavours, because if the wound through the skin and fascia be kept from healing by the introduction of a strip of lint, or of a bit of drainage-tube, the pus will soon find its way into the channel of escape thus provided for it. The cavity of the abscess should be syringed out from time to time, according to the amount of discharge, with some suitable astringent or antiseptic lotion; and care must be taken that a free opening is maintained as long as pus continues to be secreted.

4. **Caries.**—In strumous children, caries of some part of the margin of the orbit is not uncommon; and, after the diseased bone has come away, we frequently see much deformity of the lids produced by adhesions between the skin and the deeper tissues, or by the contraction of cicatrices. Many of such cases require plastic operations; but each one, before any operation is undertaken, must be carefully studied in order to discover the most promising method of procedure. In a lad with inherited syphilis, the writer has seen very extensive necrosis of the orbital margin, subsequent to the partial removal, and partial absorption, of a large gummatous tumour in the cavity.

5. **Tumours.**—Tumours of the orbit may be cysts (hydatid, dermoid, or sebaceous); lipomata; gummata; sarcomata, originating in connective tissue, and presenting the characters of myxoma, or of the sarcomatous growths distinguished respectively by round and by spindle-shaped cells; or they may be gliomata, springing from the connective tissue of the optic nerve. In other instances they may commence as an apparent hypertrophy of the lacrymal gland; or they may be cartilaginous, or osseous. All alike produce protrusion of the eyeball, and limitation of its movements, together with an amount of disturbance of vision, which depends upon the degree of pressure or of stretching to which the optic nerve is subjected, or upon the degree in which the intra-ocular circulation is impeded. Many of the forms are liable to recurrence, and may thus ultimately destroy life.

TREATMENT.—All growing tumours of the orbit require removal, if possible, without sacrifice of the eyeball; but it is usually prudent to leave stationary tumours alone, more especially congenital cysts, which have frequently been found in relation to deficiencies of bone which have opened up a connection with the cranial cavity.

R. BRUDENELL CARTER.

ORCHITIS (*ὄρχις*, a testicle).—Inflammation of the testis. See **TESTES**, Diseases of.

OREZZA, in Corsica.—Iron waters. See **MINERAL WATERS**.

ORGANIC DISEASE.—This expression indicates a disease in which there is a structural change in the part affected, as distinguished from a merely functional disorder, in which no such change has been found.

ORIENTAL SORE.—**SYNON.** : Delhi Boil ; Bagdad Boil ; Aleppo Evil ; Fr. *Bouton d'Alep* ; Ger. *Beule von Alep*.

DEFINITION.—A specific ulcer of the skin, commencing as a papule, subsequently breaking down into an extending and indolent ulcer, tending to run a natural slow course, and ultimately to heal, leaving a permanent depressed cicatrix.

GEOGRAPHICAL DISTRIBUTION.—This affection is endemic in many places, chief among which may be named Asia Minor, Syria, and Mesopotamia, in which latter country, especially in Bagdad, it is probably most common. It is also found in several other countries, and has been variously named from its local prevalence ; thus in Morocco and the Sahara it is known as the Biskra boil or sore (*Bouton de Biskra*), and in India as Delhi Boil, Moulton Sore. It occurs also in Arabia, Persia, Egypt, islands in the Mediterranean, and lately it has been described as common in Bahia, Brazil, from which it would appear that it is not invariably an Eastern affection.

It is more common in cities than in the country, and seems to be influenced in the frequency of its occurrence by sanitary conditions, as Manson mentions its marked decrease in Delhi immediately after certain sanitary improvements in the city. Hirsch states that it is more common at the commencement of the colder season of the year.

ÆTIOLOGY AND PATHOLOGY.—Although up to the present time no micro-organism capable of propagating the sore has been isolated, there is no doubt, from the communicability of the disease by means of inoculation with the discharge, in the case of both man and the lower animals, that it is due to a specific germ, and that no constitutional condition has more than a predisposing influence in its causation. Numerous micro-organisms, for the most part diplococci, have been described in connection with Oriental Sore ; but no one of them has been yet found capable, in pure cultivation, of producing the sore. An attack of the sore seems generally to confer immunity against future attacks, and this has led to the practice among the Jews of Bagdad of inoculation with the virus in parts of the body which are usually hidden from sight, in order to avoid the possibility of an unsightly scar on the face or other exposed part, the chance of escape from an attack of the sore at some time or other being considered very small. There is some doubt as to the absolute certainty of the immunity against subsequent infection, at all events by inoculation. Although called in many places a 'boil,' the Oriental Sore is not a furunculus ; it commences as a papule, which breaks down after a few days into an ulcer, which tends to spread for a variable time and to a variable extent, and then to slowly cicatrise. The essential pathological condition present is, according to all observers, a large de-

velopment of lymphoid or granulation-corpuscles, which infiltrate the derma between the lymphatics, blood-vessels, and sweat-glands. These corpuscles are especially numerous beneath the centre of the lesion, where they replace entirely the proper elements of the tissues. Infection is not improbably conveyed by flies or biting insects, such as fleas, and perhaps mosquitoes. The incubation-period, from infection to appearance of papule, appears from experiment to be about three to five days.

SYMPTOMS AND DESCRIPTION OF SORE.—The first appearance of the sore is in the form of an itching, shotty-feeling papule, which in a day or two develops scales on its surface ; the scales are at first thin and papery, becoming after five or six days thicker and brownish in colour, and forming a crust. After a few more days the crust either falls or is scratched off, and a shallow ulcer with perpendicular jagged edges is left. This tends to spread by further breaking down at its margins, and also in some cases by other papules in its close vicinity forming ulcers which join the original ulcer ; the resulting sore, which is generally oval in shape, thus varies considerably in size, from a diameter of an inch or an inch and a half, which is usual, to one of several inches. The surface of the sore is irregular, the discharge ichorous, and not very profuse, occasionally forming crusts. After a variable time, said to range from two or three to twelve or more months, healing commences, skin commencing to form first in the centre of the ulcer, where the effect of the germ is probably first exhausted, and spreading to the circumference ; ultimately a depressed white or pinkish cicatrix is left, which is permanent. The sores are situated generally on the hands, feet, arms, legs, or face, the last situation being a common one in young children ; there may be only one sore, or two or three, or, in some cases, many ; people of either sex, of all ages, occupations, and social conditions, are liable to attack.

TREATMENT.—Destruction of the original papule, or of the ulcer when small, by means of caustics, or the actual cautery, has been advocated, but it does not appear that any great measure of success has been thus attained. It is probable that were any radical measure likely to be followed by success it would be found in clean excision of the original papule, such excision to include, of course, the whole thickness of the skin and also the subcutaneous fascia ; this operation, however, does not seem to have been tried. All writers are agreed that the best treatment, having regard to the fact that the affection is one that must run its course, is by soothing, palliative measures ; poultices, or hot boric-acid fomentations if the surface of the ulcer be foul, followed by iodoform-ointment or any simple antiseptic dressing. Manson states that, in the experience of Andrew Duncan, a piece of thin sheet-lead strapped over the ulcer is often very successful, a mode of treatment which formerly was a favourite one in certain forms of small irritable ulcer in England. Although the constitutional condition of the patient has probably nothing to do with the causation of the disease, it may have a good deal to do with the rate and regularity of the healing process ; any state, therefore, such as one of anæmia or debility, betokening a deficiency of power of repair, should receive appropriate treatment.

MAX. F. SIMON.

ORIENTATION.—This term is used in medicine to signify the power possessed by a sane person of accurately judging of his relationship to surrounding objects.

OROYA FEVER.—See CARRION'S DISEASE.

ORTHOPNŒA (*ὀρθός*, erect; and *πνέω*, I breathe).—A form of difficult breathing, in which the patient is compelled to assume the sitting or erect posture.

ORTHOTONOS (*ὀρθός*, straight; and *τόνος*, a stretching).—A form of tetanic spasm, in which the body is rigidly extended. See TETANUS.

OSMIDROSIS (*ὀσμή*, odour; and *ἰδρώς*, sweat). A condition of the perspiration in which it yields an unusually strong or fetid odour. See SUDORIPAROUS GLANDS, Disorders of.

OSSEOUS SYSTEM, Diseases of.—See BONE, Diseases of.

OSTEITIS (*ὀστέον*, a bone).—A synonym for inflammation of bone, which may be of various kinds. See BONE, Diseases of.

OSTEITIS DEFORMANS.—See BONE, Diseases of.

OSTEOMALACIA (*ὀστέον*, a bone; and *μαλακός*, soft).—A synonym for mollities ossium. See MOLLITIES OSSIIUM.

OSTEOMYELITIS (*ὀστέον*, a bone; and *μυελός*, the marrow).—A name for inflammation of the médulla of bone. See BONE, Diseases of.

OSTEO-SARCOMA (*ὀστέον*, a bone; and *σάρξ*, flesh).—A sarcoma with a tendency to ossification. See BONE, Diseases of; and TUMOURS.

OTALGIA (*ὄς*, *ὠτός*, the ear; and *ἄλγος*, pain). Pain in the ear: earache. See EAR, Diseases of.

OTITIS (*ὄς*, the ear).—Inflammation of the ear. See EAR, Diseases of.

OTOLITH.—See CONCRETIONS.

OTOMYCOSIS.—A chronic inflammation of the external ear induced by the presence of a fungus. See EAR, Diseases of, p. 434.

OTORRHOEA (*ὄς*, the ear; and *ῥέω*, I flow).—Discharge from the ear, usually purulent. See EAR, Diseases of.

OVARIES, Diseases of.—SYNON. : Fr. *Maladies des Oaires*; Ger. *Krankheiten der Eierstöcke*; *Krankheiten der Ovarien*.—Under the heads MENSTRUATION, Disorders of, and HYSTERIA, much information may be found upon subjects which might be included among the diseases of the ovaries.

Total removal of the ovaries brings about total suppression of menstruation, but this operation is often impracticable or liable to fail for reasons which will be explained under 'Abnormalities.' On the other hand, when, in retro-peritoneal hysterectomy, both ovaries are saved, the patient is spared the discomforts of a sudden premature menopause, such as often, though not invariably, results when both ovaries are removed with the uterus. Yet

observers of experience have found that where the ovaries have been left, their atrophy with consequent menopause always follows within a year or two, it all the tissue of the body of the uterus be removed, and nothing but the cervix left in the stump.

The ovaries swell at about the menstrual period. This phenomenon has been observed when an ovary lies in a hernial sac. In a healthy subject, the ovaries do not seem to be tender during the catamenia, notwithstanding their engorgement. It is best to delay an operation when on the appointed day the period appears prematurely, unless, indeed, the operation be urgent. The vessels of the broad ligament will be found congested and the ovaries swollen, yet their removal under the circumstances seldom causes marked local or general disturbance. Hysterectomy for fibroid tumours is also best delayed if an unexpected period comes on. The more blood there is in the uterus, the greater the risk in that operation, and both uterus and ovaries are certainly engorged during the period. The appearance of true, typical menstruation with distinct molimen, during the first few days after ovariectomy, hysterectomy, and many other operations is usually associated with a distinct rise of temperature, but no other sign of constitutional disturbance. See also PAIN IN VISCERAL DISEASE.

The diseases of the ovaries which will be specially alluded to in this article are as follows: (1) Abnormalities; (2) Displacements; (3) Disturbances of Circulation; (4) Acute Inflammation; (5) Chronic Inflammation; and (6) Tumours, including Cysts.

1. Abnormalities.—Absence of one ovary has been found in subjects where the uterus and the opposite ovary were perfectly well-developed. Total absence of both ovaries and even of the uterus as well has been noted in adults physically and mentally sound. As a rule, however, it is otherwise; and in cases of sexual derangement the genital tract should always be explored. Dysmenorrhœa and dyspareunia have been observed in patients with ill-developed ovaries. A third or accessory ovary has been detected by many authorities, but the term is often applied to a mere lobe projecting from the normal organ and sometimes pedunculated. The 'accessory ovary,' relatively very rare, has been the accredited cause of persistent menstruation after the removal of both normal ovaries or after double ovariectomy. But ovarian tissue is often found in the ovarian ligament, which forms part of the pedicle left behind after these operations. Hence persistent menstruation under such circumstances is not mysterious.

2. Displacements.—Congenital or acquired displacements into the inguinal canal or prolapse into Douglas's pouch have been frequently detected. The 'ovary' sometimes proves to be a testicle. A true ovary has been found in the sac of a femoral, umbilical, obturator and gluteal hernia respectively (see OVARIES, Herniæ of). Non-descent of the ovary into the pelvic cavity is, on the contrary, very rare. It has been noted in about three adults, and causes no inconvenience.

3. Disturbances of Circulation.—Hyperæmia, when not excessive, may be considered as an essential part of normal menstruation. A very little excess may lead to the formation of a large clot in an unbroken Graafian follicle, or extravasation into the stroma of the ovary (*ovarian apoplexy*). In typhoid fever, Asiatic cholera, scurvy, phosphorus-

poisoning, severe burns, and in the acute specific fevers, these hæmorrhages are frequent. The ovarian stroma may be soaked in blood, and the affection is usually bilateral. Undoubtedly it accounts in some of such cases for sterility in patients that recover. In some instances, apoplexy into the follicles is caused by torsion of the ovary and consequent obstruction to its blood-supply. Alleged cases of rupture of the ovary from internal hæmorrhage and consequent development of hæmatoma of the broad ligament, or of an intraperitoneal hæmatocele, have been published. Most probably they were, in reality, instances of rupture of an extra-uterine fetal sac.

4. Acute Inflammation.—The ovary is very subject to acute inflammation, oöphoritis being far more frequent than orchitis notwithstanding the external and more exposed situation of the testicle. The poisons developed by infection during child-birth and abortion, as well as the virus of gonorrhœa, are very apt to cause inflammation of the ovary. Primary acute tuberculosis of the ovary seems unknown, but the ovary is easily infected from the Fallopian tube, a common seat of primary tubercular infection. Acute oöphoritis is not often caused by mere chills, as was once supposed. Abscess or diffuse suppuration of the stroma of the ovary may occur in puerperal septicæmia. Gonorrhœal pus from the tube may infect the ovary through a ruptured follicle.

SYMPTOMS.—This disease is usually accompanied by inflammation of the tube and adjacent peritoneum. There is pain over the pubes, tenderness on pressure over one iliac fossa, and often vesical irritation. On bimanual palpation it is easy to detect the tense, enlarged and extremely tender inflamed ovary. In recent cases the ovary is freely movable; but its mobility is often impaired in a few days by adhesions.

TREATMENT.—Rest and appropriate remedies for inflammation will rapidly cure an uncomplicated case of acute oöphoritis. The convalescent patient must be very careful of her health, especially during subsequent periods. The patient should rest on her back, with the hips raised and thighs flexed and supported by a pillow. At first, fomentations over the iliac fossæ will be needed, followed by linseed-meal and turpentine poultices and hot douching. The douche, in some subjects, gives pain and must be discontinued. The patient should take saline purgatives and bromide of potassium. The condition of the ovary must be ascertained from time to time by gentle bimanual palpation. The inflammation is not cured till the ovary is quite painless, and, indeed, hardly to be detected by the touch. Uncomplicated acute oöphoritis never demands operation. Acute ovarian abscess, denoted by persistence of pain and swelling, with rise of pulse and temperature, is best left alone, and allowed to become chronic before it is opened, as at first the pus is very septic. This condition, however, is hard to distinguish from pyosalpinx, and is almost always complicated. An ovarian abscess, if opened when acute, must be reached from the vagina, not through the abdomen.

5. Chronic Inflammation.—This disease is much more frequent than typical acute oöphoritis, and is often associated with intercurrent attacks of subacute inflammation. It can hardly ever be uncomplicated, it tends to set up inflammation of the adjacent peritoneum which causes adhesions, and may also seal up the abdominal end of the Fallopian tube;

on the other hand, it is a very common result of tubal inflammation. The changes induced in the ovary itself by inflammation vary. Sometimes the follicles are completely or functionally destroyed, and the stroma hypertrophies; the ovary feels enlarged, but not very tender. In another form the follicles remain, but cannot burst, then 'small cystic degeneration' sets in. It is hard to distinguish such an ovary clinically from an incipient cystic tumour; there is little tenderness. In a third form true cirrhotic changes occur. This is the gravest variety; it cannot cause death but always sets up local trouble, especially amenorrhœa, and is not rarely the source of bad neuroses. Tuberculosis of the ovary is always secondary to tuberculosis of the peritoneum or tube, and usually assumes the characters of chronic inflammation. A 'cold abscess' sometimes develops in a tuberculous ovary.

TREATMENT.—The treatment must be the same whether chronic inflammation has succeeded an acute attack or has merely increased in intensity or duration after repeated recurrence. Known causes must be avoided, great attention paid to the general health, and counter-irritation employed. Among the best sedatives are belladonna and the bromides. When an ovary, heavy and enlarged from old inflammation, prolapses, an elastic ring-pessary should be applied for a few weeks. The medical attendant should try all means before thinking of removal of the diseased ovary. When there are widespread complications, especially pyosalpinx, the case is different, although in many instances the patient may be cured by medication.

6. Tumours.—Cystic tumour of the ovary is one of the most frequent diseases to which that organ is subject. For practical purposes of diagnosis and treatment cystic tumours of that ovary may be divided into *simple or unilocular*, and *compound or multilocular*. Under the simple form is included *dropsy of the follicles* or *hydrops ovarii*, which is pathologically not a new-growth, but a result of chronic inflammation of the 'small cystic degeneration' type. Yet a dropsical ovary may attain to a diameter of over three inches. As a rule, however, the common ovarian cyst, especially in its most benign and best-known variety, is unilocular only in the sense that one loculus greatly exceeds the others in capacity. It may hold many pints of fluid, while the others contain under an ounce or a drachm; hence they are of no account to the surgeon, as, when the predominant loculus is emptied during ovariectomy, the rest of the tumour can be extracted with the greatest ease if non-adherent. Even in this sense the more unilocular the tumour the more pathologically innocent it will be; one grave exception must be borne in mind, namely, the true *papillomatous cyst*, semi-malignant in its clinical characters. This kind of cyst is often unilocular, and never consists of more than a few loculi. But while the practically unilocular ovarian cyst usually rises freely into the abdomen, the papillomatous cyst proper burrows more or less into the pelvis. In dermoid cysts one loculus sometimes, but not always, predominates.

The multilocular cyst of the ovary is pathologically an adenoma or glandular tumour. It is the commonest form of cystic tumour of the ovary, and is identical with the practically unilocular type just noted, excepting in two important features. No one loculus much exceeds in capacity that of any other; and from the inner wall of the loculi glandu-

lar growths spring freely. The smaller loculi are stuffed with them, so that hardly any cavity is left. On section the growths appear soft and gelatinous, and much of their glairy secretion hangs on to the knife and exudes on pressure. These glandular masses are not malignant; but malignant changes may take place in a multilocular tumour. Sometimes a multilocular cyst is made up of distinct loculi grouped like a pile of old spherical cannon-balls. In such a case the operator should see that the tumour is carefully examined after removal, as it sometimes contains malignant, and often dermoid, elements. *Dermoid cysts* are more frequent in the ovary than in any other organ; in this form one loculus often exceeds the others in capacity. They contain liquid and solid fat, teeth, bone, hair, skin with sebaceous and sweat-glands, and even more complicated structures. The surgeon chiefly regards their greasy, and sometimes fetid, contents, which must not be allowed to escape into the peritoneal cavity. Old adhesions to intestine are specially dangerous, and involve infection of the tumour, and the hair or bone may find its way into the bladder. Ovarian cysts in infants and little girls are usually dermoid.

The *fluid contents* of ovarian cysts was the subject of much study in the days when tapping for diagnosis was practised. When free from blood and broken-down glandular tissue, the fluid of the common ovarian cyst is glairy and greyish, or faint greenish-grey in colour, and contains paralbumen, while ascitic fluid is pale yellow, not very glairy, and contains much serum-albumen. But old hæmorrhages from the cyst-wall turn ovarian fluid dark, and it often assumes a very characteristic chocolate-brown tint. On the other hand, opaque dead-white masses, consisting of collections of glandular matter, are common in the fluid of multilocular cysts. The fluid of dermoid cysts varies; sometimes it is glairy, and bears all the characters of the fluid of a common multilocular cyst, but even then rarely fails to bear fatty globules; sometimes it is pure fat, solidifying on cooling, but most commonly it is a pulraceous mixture of ovarian fluid, fat, and sebaceous matter. Hairs, rarely absent, further betray its character.

In the pure papillomatous ovarian cyst, relatively malignant, and nearly always difficult to remove, and in the parovarian cyst, perfectly innocent and one of the easiest to extirpate of all pelvic tumours, the fluid is alike watery, of very low specific gravity, and holds chloride of sodium in abundance.

Solid Ovarian Tumours.—*Fibroma* is not exceedingly rare. It has often been seen in girls; in mature women it has been mistaken for a pedunculated uterine fibroid, but unlike fibroid it is apt to cause ascites. Its removal is, as a rule, easy, and it is perfectly innocent. *Myoma* is usually small, clinically it resembles fibroma. *Sarcoma*, often bilateral, may appear as a very large solid tumour. Secondary cysts develop, and hæmorrhages occur in its substance. *Carcinoma* is more common in the ovary than sarcoma. The abundant glandular elements in the common ovarian cyst and the epithelium of the papillomatous cyst furnish materials for cancerous changes. As in sarcoma, this disease is often bilateral. *Free papilloma* of the surface of the ovary, never encysted even at its origin, is clinically very malignant. But if the surgeon can extirpate the affected ovary it does not recur. The opposite ovary is usually involved and should be

removed if it bear the least trace of papilloma. If the papillary growth has spread over the adjacent viscera, it will probably destroy the patient, yet instances are known where it has withered after removal of the affected ovary.

COMPLICATIONS.—*Inflammation, hæmorrhage, and twisting of the pedicle.*—Any ovarian cyst, simple or compound, may be the seat of inflammation either on its surface, when the symptoms do not differ from those of peritonitis, or in the cyst-wall or lining membrane, when (without any peritonitis) there may be pain and considerable fever, sometimes followed by rigors and suppuration. Hæmorrhage into one or more of the cyst-cavities may lead to all the symptoms and effects of internal hæmorrhage. The growth and nutrition of the tumour may become greatly modified, from twisting of the pedicle, which obstructs the circulation of blood in the vessels of the tumour. In some cases twisting of the pedicle may be followed by a complete separation of the tumour from its ordinary supply of blood. In this condition the tumour is nourished by vessels in the omentum, abdominal wall, or some other structure adherent by its peritoneal coat to the tumour. True gangrene of an ovarian tumour from twisting of its pedicle is now known to be rare, for the warmth of the peritoneum maintains its vitality, and adhesions rapidly form and carry nutrition to the growth. Acute and sub-acute torsion of the pedicle cause severe abdominal pain, often accompanied with vomiting. When the tumour has already been diagnosed, these symptoms are easy to interpret; in some cases the pain and sickness have led to the detection of the tumour, while in other instances they have been falsely attributed to intestinal strangulation. Inflammation of the cyst, and still more certainly twisting of the pedicle, leads to the development of adhesions to the pelvic and parietal peritoneum, the omentum, bladder, and intestines. *Rupture of an ovarian cyst* is not rare. It is produced sometimes by external agencies, but often more or less through pathological changes in the tumour itself. The thin-walled parovarian cyst is very liable to burst, and this accident may cure the disease, unless papillomatous growths are present inside the tumour, in which case there will be great danger of diffusion of the growths over the peritoneum. The common ovarian cyst sometimes bursts from external violence; even in such cases the immediate effects are seldom alarming; fatal hæmorrhage and even very severe shock have been reported, but rarely occur. The common ovarian cyst is very apt to give way through degenerative changes in its walls, such as inflammatory softening, atrophy of the tissues from changes in its ill-developed vessels and destruction of the stout fibrous tissue in the walls by the free development of minute cysts. Pints of ovarian fluid may escape rapidly into the peritoneal cavity, yet cause remarkably little pain and disturbance. For a short time there is dulness in the flanks and resonance anteriorly, as the patient lies on her back, while before the accident the reverse condition existed. But the effused fluid is rapidly re-absorbed. The rent in the cyst usually heals, or is stopped up by adhesion to adjacent structures, and the cyst fills up again. Allied to rupture, but much rarer and far more serious, are cases where, after adhesion of the cyst-wall to intestine or bladder, the cavities of the cyst and the adherent organ communicate, and the ovarian fluid escapes by the

anus or urethra. The *diagnosis* of rupture of an ovarian cyst is easy when the clinical history is reliable, and it is certain that an ovarian tumour existed before the accident. But when there is nothing certain, save that the patient believes that the abdomen, previously swollen, has grown smaller in a single day or night, there are numerous sources of fallacy. Phantom tumour, tympanites, temporary dullness in the flanks from loaded intestine, and tubercular peritonitis with encysted collections of peritoneal effusion must be borne in mind.

SYMPTOMS AND DIAGNOSIS.—Spencer Wells used to insist that, clinically, the main questions for consideration in cases of fluctuating abdominal tumours are whether the fluid be contained in a cyst, or whether it be in the peritoneal cavity, either free or limited by visceral adhesions. In solid tumours their seat and nature must be investigated. See ASCITES.

A typical ovarian cyst is not hard to diagnose. It lies centrally on the abdomen, rising from the pubes upwards, sometimes reaching as high as the ensiform cartilage. It is freely movable, dull on percussion, and fluctuates. The wave of fluid cannot be made to pass beyond the line of dullness on percussion. In very multilocular cysts there is often difficulty in detecting fluctuation. In a case of ovarian cyst there is resonance in the flanks unless it happen that there be also free fluid in the peritoneum, or that the colon be loaded. Both these conditions have led to error in diagnosis. The cyst usually reaches below to the pelvic brim, the uterus is found, on passing the sound, to be separate from the tumour, and to lie behind and below it; not rarely its body is forcibly anteverted. Some cysts burrow in the broad ligament; then their lower limits can be felt low down in the pelvis, the uterus is pushed to one side, or, very often, displaced forwards and upwards. The abdominal part of a burrowing ovarian cyst is never freely movable.

Other Abdominal Tumours.—The abdominal growths most liable to be mistaken for ovarian tumours are fibroid or fibro-cystic tumours of the uterus, and cysts or solid tumours of the spleen, liver, pancreas, or kidney. Pregnancy, normal or extra-uterine, may also be mistaken for an ovarian tumour. We must remember that it is not rare for pregnancy to occur in a woman subject to an ovarian or uterine tumour; therefore in examining any woman who has an abdominal tumour the ordinary signs of pregnancy must be borne in mind. The frequency of fecal accumulations, or of tympanitic distension of the intestines, with thick or rigid abdominal walls and a fat omentum, must also be remembered and excluded. The observer may be misled by fatty tumours which form in the omentum or develop from appendices epiploicæ. Large fibroid and fibro-sarcomatous tumours of the abdominal wall may be mistaken for solid ovarian growths. Cysts of the urachus are not always easy to distinguish from ovarian cysts. Any condition which produces a swelling in the abdomen or pelvis must be borne in mind when the ordinary signs of an ovarian cyst or tumour are not sufficiently characteristic to exclude doubt. In nervous subjects, where the abdominal muscles resist and interfere seriously with palpation, free purgation followed by careful examination under an anæsthetic is advisable in order to avoid error. In such a case it often happens that no tumour exists, the abdominal swell-

ing being due to tympanitic distension and loaded bowels.

In advanced malignant disease, when the new growth has extended beyond its original seat, it is often impossible to determine whether the ovary gave origin to the malady. In the unfortunate patient's interests the question of diagnosis has become of no import. In such cases, the disease being evident, it is bad surgery to make an exploratory incision. The mere handling of cancerous structures may set up peritonitis; septic infection which cancerous tissue cannot resist is very probable; and if neither complication follows, the abdominal wound is liable to malignant infection through the suture-tracks, and then the patient suffers all the horrors of external cancer from which, if left alone, she would be spared. If there be much dropsy tapping will relieve. On the other hand, when there is no evidence of hopeless malignancy, exploratory tapping is to be avoided. It involves as much or in many cases more dangers than those which attend careful exploration through an abdominal incision.

PROGNOSIS AND TREATMENT.—The thin-walled parovarian cyst, independent of the ovary, has disappeared after rupture or after a single surgical tapping. Thomas Keith advocated the tapping of parovarian cysts, but they often fill again and occasionally contain papilloma, so that tapping involves great risks and loses valuable time. Operation is easy and satisfactory. All true ovarian tumours destroy life after months or even years of discomfort and distressing symptoms; to this rule there are but few if any exceptions. Early removal renders the operation as easy and as safe as possible; late removal involves great surgical difficulties and subsequent danger, yet it may save an otherwise doomed patient. Error in diagnosis often leads to the detection of a tumour not ovarian, but nevertheless quite as necessary to remove.

Medical treatment is now almost synonymous with preparation for operation. In urgent cases ovariectomy must be done at once, however bad the patient's condition. But as a rule there is time for medication. Thus chronic or acute bronchitis and pneumonia may require treatment where there is a cyst or solid tumour not bulky enough to cause dyspnoea. The urine should always be carefully examined. Albuminuria and diabetes mellitus require appropriate treatment. The bowels in particular must be attended to, and the large intestine freed from scybala. Inflammation of a cyst clearly due to a blow or fall is, perhaps, best treated by a few days' rest and local treatment; but most complications signify that ovariectomy is urgent.

Ovariectomy.—The average risk of ovariectomy in a large number of cases, including the most and the least favourable, has been diminishing for many years past. Through improvements first in antiseptic and then in aseptic surgery, ovariectomy has become one of the most successful of all capital operations. The mortality has fallen to under five per cent. in the hands of experts. In the case of simple or non-adherent multilocular cysts, there should be no mortality; occasionally a case may be lost where the patient is suffering from some other disease aggravated by the bulky tumour. Very large and widely adherent tumours, only removable with extreme difficulty, may nevertheless be safely extirpated if the patient be fairly strong, and many very weak subjects can be pulled through by judi-

cious after-treatment. In certain cases there is always a risk of death, so that out of ten such cases one or more will probably be lost. Under this head suppurating tumours, adherent dermoids, and, above all, malignant ovarian growths are included. A cyst containing pus cannot be removed without distinct risk, nevertheless experience shows that the danger is not very great. There is much greater peril when a dermoid closely adheres to intestine so that its greasy contents have become infected. Bone and masses of hair, fat and sebaceous matter may project into hollow viscera, which are unavoidably damaged when the surgeon sets them free. As a rule, however, this unfavourable condition does not exist, and the dermoid can be removed with ease and safety. A malignant tumour may often be removed with success, and the patient may enjoy months or years of relative comfort. But the danger of removing a malignant tumour is great. This fact is proved by statistics collected at institutions where the pathology of the growth and the after-history of the patient can both be accurately observed and recorded. In Olshausen's practice the mortality *more or less directly* from operation in 100 cases of sarcoma, carcinoma, and malignant or clinically malignant papilloma was 28. Such reports are gloomy but they are also reliable.

The removal of a tumour of one ovary does not appear to affect the number of pregnancies, nor the sex of the children, nor the occurrence of twin pregnancy. Spencer Wells was many years ago in a position to note that the removal of both ovaries, subject to tumour, leads only in exceptional cases to obesity, severe premature menopause, and general neuroses. The relation of double ovariectomy for tumours to removal of both ovaries for the cure of neuroses or the checking of the growth of a uterine myoma is uncertain and deserves close study. We know that double ovariectomy is highly successful, and that the patients rarely have anything to complain about afterwards. Removal of the ovaries for neuroses seems unjustifiable and rarely successful, but though severe and aggravated neuroses may follow the operation, they at least existed before, even if only in a milder form. Many advocates of hysterectomy for uterine fibroids, without removal of the ovaries, declare that when those organs are also removed distressing menopause symptoms are very likely to ensue; but this assertion remains to be proved, as it is not certain that the patient, as a rule, fares worse than after double ovariectomy; and where neurotic symptoms have been noted, it is still less certain that they are due to the loss of the ovaries and not to the removal of the body of the uterus and damage to the innervation of the cervix.

ALBAN DORAN.

OVARIES. Herniæ of the.—In the majority of cases displacements of the ovaries occur downwards into Douglas's space, and in such instances the left ovary is the one usually displaced. The next most frequent forms of ovarian herniæ are those occurring in the inguinal regions, either above Poupart's ligament, or, as is more commonly the case, following the canal of Nuck downwards and forwards and presenting in the labia. In the first named, or directly downward displacement, the ovary, on vaginal examination, may be discovered in the recto-vaginal fossa as a small ovoid, firm, elastic, and highly sensitive tumour, bulging into the post-cervical *cul de sac*.

ÆTIOLOGY.—Although in some instances congenital, ovarian herniæ more usually occur in patients whose abdominal parietes have been relaxed and viscera compressed by repeated gestation, or want of due support after parturition. They may also be induced by causes similar to those of other herniæ, such as the violent muscular efforts of the second stage of labour, lifting a heavy child, or straining at stool. In displacement downwards into Douglas's space, the cause of the protrusion is, however, generally gynæcological rather than obstetric, the result of the *vis à tergo* of abdominal or uterine tumours, or of the tension on the appendages occasioned by displacements of the uterus.

SYMPTOMS AND DIAGNOSIS.—Ovarian displacements, when inguinal, may be mistaken for enlarged glands, or as an enterocele or epiplocele; when labial, for other tumours in that situation; when downwards, for pelvic abscess or hæmatocele, retroversion or retroflexion, or for a fibroid growth from the posterior uterine wall. The sudden occurrence of a small ovoid tumour, possessing the physical characteristics just referred to and located in one or other of these situations, accompanied by constitutional and nervous disturbance, with a peculiar dull sickening pain, aggravated into acute suffering at each menstrual epoch, and a coincident increase of size then manifest, together with the intense tenderness or nausea generally evinced during any examination of the part, are sufficient to enable a correct recognition of the nature of the case to be made by any competent gynæcologist.

TREATMENT.—When the ovarian hernia takes place at either of the abdominal rings, it may in some instances be reduced by taxis. In the majority of cases, however, these displacements are already irreducible when discovered; and even in the cases in which reduction is possible, the retentive pressure of an ordinary truss is too frequently neither endurable nor effectual. In such instances the extruded ovary should, if feasible, be protected from further protrusion or external injury by a well-fitting hollow truss. But before this an attempt should always be made to lessen the local hyperæsthesia of the generally hypertrophied displaced gland by topical sedative applications, and, if necessary, by leeching, &c.; while the constitutional irritation almost always present in such cases should be allayed by suitable constitutional treatment. When, however, these measures prove ineffectual in relieving the persistent, dull, worrying, aching pain so commonly associated with chronic ovarian hernia, and which at each monthly period in these cases becomes accentuated or acute—when, too, the patient's health is endangered by the nervous disturbance and constitutional irritation, we should fall back on extirpation as the only resource available. But this treatment should be regarded as exceptional; nor is the performance of oöphorectomy under these circumstances by any means devoid of risk, or to be undertaken without urgent necessity, and until a fair trial has been first made of other remedial or palliative measures.

With regard to the treatment of prolapse of the ovary into Douglas's space, this caution is especially applicable. In considering the management of this displacement, its causes must be carefully borne in view. Pressure from above downwards of a uterine or ovarian tumour, or the traction of a uterine displacement on the broad ligaments, must be removed or relieved before any successful re-position of the

prolapsed ovary can be made. When the dislocation is due to some accidental circumstance, or to a relaxed state of the parts occasioned by constitutional causes, we may, with greater probability of permanent success, attempt to return the displaced viscus and retain it *in situ*. For this purpose the patient—being first anaesthetised in order to permit of the necessary manipulation of the generally highly sensitive and tumefied ovary—should be placed in the left lateral semi-prone position, when by gentle, steady, conjoint digital pressure through the rectum and vagina, upwards and forwards, we may be able to lift the extruded ovary out of the post-cervical recto-vaginal fossa, and to push it up into its normal position, where it may then be retained by a suitable support. Failing the possibility of such re-position, however, if the local and constitutional effects of the displacement are urgent and otherwise irremediable, the practitioner as a *dernier ressort* must remove the ectopic gland.

THOMAS MORE MADDEN.

OVERLYING. — **SYNON.**: Fr. *Etouffer un Enfant*.—Overlying is an accident which, it is alleged, not infrequently happens to young children, whereby they are killed by suffocation. On an average rather more than four hundred children per annum are registered in London as dying from 'overlying' in bed. The Registrar-General in his report for 1890 states that 1,544 children, mostly in the first year of life, died from 'suffocation in bed'; that this mode of death is on the increase; that it is more frequent in the winter than in the summer; and that the proportion of deaths due to this cause is more than twice as high on Saturday night as on any other night in the week. The only explanation for the pre-eminence of Saturday is the fact that on this day wages are paid and drunkenness is common. The *post-mortem* signs of overlying are those of suffocation. Evidence that a child has really died from this cause is afforded by (1) the *post-mortem* appearances of death from asphyxia; (2) the absence of any other mortal disease; (3) the absence of evidence of any cause of asphyxia other than overlying.

The statement that a child has been overlain should be received with caution. It is reasonable to suppose that a vigorous child would escape from a suffocating position beneath the bed-clothes, or the body of its nurse, by its own efforts; or at least succeed, by its crying and struggling, in waking its nurse. On the other hand, a very weakly child, whose lungs possibly have only partially expanded, might be killed by a very trifling cause, such as the position of its mouth and nose against the body of its nurse, or the accidental temporary obstruction of its air-passages by the bed-clothes. A medical witness, before committing himself to a theory of death from overlying, must consider all the points alluded to above, and must take care not to bring a charge of almost criminal carelessness against a careful nurse, or allow an act of wilful murder to pass under the guise of accidental death.

G. V. POORE.

OXALIC ACID, Poisoning by.—See POISONS.

OXALIC ACID IN URINE.—**SYNON.**: Oxaluria.—There is reason to believe that the oxalic acid which is constantly, or almost constantly, present in human urine is in part derived directly from the food, and is in part a product of metabolism

within the body. That the oxalate is in part derived from food has been clearly demonstrated, and analytical results are here in full accord with the clinical observation that a deposit of crystals of calcium oxalate is wont to follow the ingestion of articles of diet, such as rhubarb, which are specially rich in this substance. The view that some of the oxalate excreted is a product of metabolism is based upon observations, chiefly carried out in Salkowski's laboratory, on its presence in the urine of fasting dogs, and in that of human beings who have for some time taken an oxalate-free diet. It should be mentioned, however, that Gaglio, Bunge, and Dunlop have observed the disappearance of oxalic acid from the urine of persons on diet of this description. Granting that some of the excreted oxalate is endogenous, it is clear, from the observations of Salkowski and others, that it is not a product of the metabolism of carbohydrates or of albuminous substances; whereas a food rich in nuclein, such as thymus, was found by Lommel to cause a conspicuously increased output. Salkowski therefore thinks it highly probable that both oxalic and uric acids are products of nuclein-metabolism, the former being probably formed by the oxidation of the latter. However, Stradomsky, working with Salkowski's new method of estimation, failed to obtain an increased excretion of oxalic acid as the result of a diet rich in nucleo-albumen, and looks upon the gelatin in the tissues and kreatin as the most probable parent-substances of the endogenous oxalic acid. As to the influence of disease upon oxalate excretion little is at present known, and it is clear that any such influence will be chiefly exerted upon that portion of the excreted oxalate which is formed within the body. Diabetes mellitus and jaundice are conditions in which increased excretion has been noted, but Lommel has recently failed to confirm this observation.

The acid sodium phosphate appears to be the agent concerned in holding calcium oxalate in solution in the urine, and it cannot be assumed, without direct proof, that the deposition of crystals of the latter salt necessarily implies its presence in excess. However, Dunlop found that when such deposition takes place there is usually an increased output.

In paroxysmal hæmoglobinuria sediments of calcium oxalate are frequently met with, as also in many cases of so-called 'physiological albuminuria.' Prout and Begbie called attention to a group of symptoms which are often associated with deposits of these crystals, and described a definite 'oxalic acid diathesis.' The symptoms described are such as usually accompany acid dyspepsia, and Dunlop seeks to explain their association with oxaluria by the more free absorption of calcium oxalate from the food, in consequence of the hyperacidity of the gastric contents. Such symptoms are met with apart from oxaluria, and are often wholly wanting in cases in which the urine continuously deposits a sediment of calcium oxalate.

The deposited crystals are usually minute, and are not coloured by the ordinary urinary pigments; they may, however, be tinted by bilirubin or biliverdin when these substances are present. The crystals assume several forms—(a) the common octohedra with short vertical axis, the familiar 'envelope' crystals; (b) short prisms with pyramidal ends; (c) twin octohedra; (d) dumb-bell crystals or biconcave oval discs (see URINARY DEPOSITS: coloured plates). The deposit usually forms a white

cloud resting upon the surface of the normal nodule, and may also form streaks upon the inner surface of the containing vessel. The urine is usually clear and acid in reaction. It may contain a small quantity of albumen, and the microscope may show, in addition to the crystals, a few leucocytes and even red blood-corpuscles. Free indulgence in rhubarb may even give rise to marked hæmaturia, with the passage of large numbers of calcium-oxalate crystals, and some individuals appear to be peculiarly susceptible in this respect.

Oxalate-of-Lime Calculus.—The excretion of calcium oxalate derives its chief clinical importance from its tendency to form calculi in the kidneys or urinary passages. What are the exact conditions which determine the formation of such calculi is not as yet known, but a patient whose urine deposits oxalate-sediments during long periods does not necessarily acquire calculi. Ord and Shattock, who have made a very elaborate study of the structure of these concretions, describe four chief forms: (1) Smooth polished stones, usually met with in the kidneys or renal pelvis, of a pale ashy grey, light yellow or reddish-brown colour. (2) The ordinary 'mulberry' calculi, of a reddish-brown or sepia tint, with rough tuberculated surfaces. (3) Small stones with sharp prominent spines, and (4) small stones with crystalline surfaces beset with large uncoloured crystals of calcium oxalate. Calculi of the two last-mentioned varieties are often quite minute. The dark colour which oxalate-calculi often possess appears to be derived from hæmoglobin. The stones are hard and crystalline in structure, and the nuclei often consist of large transparent crystals of calcium oxalate, or of fan-shaped elements similar to those which form the bulk of the concretion. Speaking of such calculi Mr. Cadge says, 'The great insolubility of oxalate

of lime favours the chances of its deposition in the renal tubules. It has been detected in the kidneys of the fœtus; it is especially liable to occur during childhood; and this liability decreases as age advances. In England calculi composed entirely of oxalate of lime are rare in the adult, but in India they are comparatively frequent. Mulberry calculus in the young causes intense suffering; but in the adult, notwithstanding the formidable tubercles and rough exterior, the symptoms of stone are often mild: not improbably because these projections become entangled in the muscular columns of the bladder, and the calculus is thereby fixed in position.' The symptoms of renal calculus are fully described in another article. See RENAL CALCULUS.

TREATMENT.—Microscopic 'mulberry' calculi, were it possible to detect their existence, could probably be washed away and carried off by diluents and diuretics; but a palpable stone demands surgical treatment only.

That part of the oxalate-excretion which is directly derived from food can, of course, be controlled by suitable dieting, the most obvious indication being the avoidance of vegetables, such as rhubarb and spinach, which are known to be rich in oxalate. The probability of the origin of some of the excreted oxalic acid from uric acid and nuclein suggests the desirability of avoiding food rich in nucleo-albumens. Hyperacid dyspepsia when present should be treated by appropriate means, such as the administration of acids before, or alkalis after meals.

A. E. GARROD.

OXYURIS.—See ENTOZOA.

ÖZ/ENA (ὄζαινα, a fœtid polypus in the nose; from ὄζω, I stink).—See NOSE, Diseases of.

P

PACHYDERMIA LARYNGIS.—See LARYNX, Diseases of, p. 853.

PACHYMENINGITIS (παχύς, thick; and μῆνιγξ, a membrane).—A synonym for inflammation of the dura mater of the brain and of the spinal cord. See MENINGES, CEREBRAL, Diseases of.

PAGET'S DISEASE.—Malignant dermatitis of the nipple (see NIPPLE, Diseases of). The term is also sometimes used as a synonym for osteitis deformans.

PAIN IN VISCERAL DISEASE.—The pain of visceral disease may belong to one of three groups: (1) It may be as local as the pain produced by a bruise or a burn, and be situated directly in the affected part. Such local pain, associated with deep tenderness over the inflamed area, accompanies inflammation of any serous membrane, such as the pleura, peritoneum, or pericardium. (2) It may be referred to the termination of some nerve-trunk implicated in the disease, as, when the elbow is struck, the pain is felt in the little finger. Thus, if a nerve-trunk passes through an inflamed area, the pain will

be felt not only at the inflamed point, but also within the peripheral distribution of the affected nerve. Moreover, the area supplied by the peripheral branches of this nerve may become tender to light touch. In this way the pain of a pleurisy may be situated in the abdomen. (3) Painful impressions may be conducted up the sensory fibres of the sympathetic into the central nervous system, and then referred to the peripheral distribution on the surface of the body of those nerve-fibres that enter the same segment. This is the true visceral reflected pain that forms the main subject of this article.

§ 1. **Method of Examination.**—In visceral disease we have to deal mainly with pain that is either local or reflected. *Local pain*, as its name implies, is characterised by being situated over the focus of disease, and is usually accompanied by tenderness on deep pressure or on percussion.

True *visceral referred pain* is situated over spots of the body that bear no direct relation to the position of the disease. Should the pain be severe, or have lasted for some considerable time, these spots possibly will become superficially tender. Gently pinching the skin and subcutaneous tissue over these spots between the finger and thumb then produces

PLATES X. and XII.

The areas coloured Red or Blue are those affected by the reflected pain and superficial tenderness of visceral disease. Those coloured Black do not stand in direct connection with any organ and can only become tender by spread. They form the upper gap (on the arm) and the lower gap (on the leg).

The following organs stand in connection mainly with the following areas :—

<i>Heart</i>	1. Ventricle	Dorsal 1 (?), Dorsal 2, 3, 4, 5.
	2. Auricle	Dorsal 5, 6, 7, 8 and (?) 9.
<i>Aorta</i>	1. Arch	Cervical 3 and 4, Dorsal 1, 2, 3, 4.
	2. Dorsal Aorta	Dorsal 5, 6, 7, 8, 9.
	3. Abdominal Aorta	Dorsal 10, 11, 12 and Lumbar 1.
<i>Lungs</i>		Cervical 3, 4, Dorsal 3, 4, 5, 6, 7, 8, 9.
<i>Esophagus</i>		Dorsal 5, 6, 7.
<i>Stomach</i>		Dorsal 6, 7, 8, 9, 10.
<i>Intestine</i>	1. Duodenum to Sigmoid Flexure	Dorsal 10, 11, 12.
	2. Rectum	Sacral 2, 3, 4.
<i>Liver and Gall Bladder</i>		Dorsal 7, 8, 9, 10 (R. side).

PLATES XI. and XIII.

These plates show the maximum spots of these areas. It is to these spots that the patient refers his pain. Over these spots superficial tenderness first appears, and they remain tender during the subsidence of the pain after the rest of the area to which they belong has ceased to be tender. Thus recognition of these maximum spots is of greater practical importance than that of the full areas which rarely appear alone in visceral disease.

pain, or, at any rate, a sensation different from that produced in normal parts of the skin by this manipulation.

A still better method of marking out the tender spots is to take a pin with a round head of such a size that it is obviously blunt to the normal skin, using the blunt end only in exactly the same way as if the point was being used to test for loss of sensation. In a favourable case the patient does not complain until the limits of the tender areas are reached, when he at once complains that it hurts, and may even cry out that he is being pricked. But in the majority of cases the patient says he knows the blunt end of the pin is being used, but it gives him pain, 'as if a bruise were being touched.' Over these areas the superficial reflexes are markedly increased. But these tender spots represent the maxima of areas that extend round the body more or less in the form of a half girdle, and, if the pain be very intense, or has lasted for a sufficient period, the whole of one or more of these segmental areas may become tender. But for clinical purposes it is a matter of little or no importance whether one of these segments be represented by the complete area of its extent, or by the maximum points.

Thus, in Plates XI. and XIII. the maximum points are given, and on Plates X. and XII. the complete areas determined by the study of the tenderness of referred pain, and the distribution of the eruption of herpes zoster (*see* p. 686).

§ 2. Reason for Cutaneous Tenderness in Visceral Disease.—When impulses pass up sensory sympathetic nerves from an organ which is diseased they set up a disturbance in the segment to which they are conducted. Now any second sensory impulse from another part, e.g. from the surface of the body which passes into this same segment, will be profoundly altered. For it no longer falls into a normal and quiescent segment of the nervous system, but into one whose activity is already disturbed. The resultant stimulus, conducted upwards towards the brain, therefore differs from that which would have passed onwards from that segment under normal circumstances. The second stimulus will appear to be exaggerated, or may perhaps undergo some actual increase in its passage through the excited segment. Thus any otherwise painless stimulation applied to the surface of the body, falling within the area supplied by fibres that enter the disturbed segment, will appear to be painful, and the skin will be said to be tender. The fact that these areas correspond so closely in extent with those occupied by herpes zoster renders it probable that they belong to the same level of the nervous system, and that the cause of the tenderness is to be sought in that portion of the nervous system which, when injured, produces herpes zoster. This has now been shown to be the ganglion of the posterior root. It is therefore probable that impulses passing from an affected internal organ up the white ramus of the sympathetic system produce an alteration in some of the cells of the posterior-root ganglion. These cells form the trophic stations for the sensory fibres from the skin. Thus painful stimuli from an internal organ produce such a disturbance in the ganglion that every stimulus from the peripheral distribution of the fibres entering that ganglion appears to be painful.

§ 3. Pain produced by Disease of Special Viscera.—Brought face to face with pain produced by disease of an internal organ, it is

necessary to determine first of all whether it be local or reflected. Attention to the following points of difference enables us to decide to which class it belongs:—

(1) Reflected pain is not only situated over some point on the front of the chest or abdomen, but also over some point behind, in the back or the loin, away from the affected organ.

(2) Reflected pain is associated with more or less tenderness of the coverings of the chest, abdomen, or back, elicited by picking up the skin and subcutaneous structures between the fingers.

(3) This superficial tenderness frequently passes round the body in a more or less horizontal band from the middle line of the back to the middle line in front (Plates X. and XII.). If less acute it lies over one or more spots, one of which is situated over the anterior, the other over the posterior aspect of the trunk (Plates XI. and XIII.).

(4) Pressure as a rule relieves this superficial tenderness.

(5) The superficial reflexes are increased over an area of superficial tenderness that accompanies visceral reflected pain.

(6) Reflected pain of the visceral type is frequently accompanied by headache and superficial tenderness of the scalp, following rules laid down on p. 1145.

(1) Local pain is confined strictly to the area of the affected organs, and does not pass round the body or through to the back.

(2) Local pain is accompanied by no superficial tenderness. But when the painful area is pressed or percussed pain is produced, the amount of such tenderness depending on the force applied.

(3) This deep tenderness does not extend beyond the limits of the serous membrane inflamed or outside an area over which direct pressure can be brought to bear on the serous membrane or organ affected. It cannot therefore be elicited over the posterior aspect of the trunk unless the inflammation has extended into the tissues of the back.

(4) Pressure increases deep tenderness.

(5) The superficial reflexes are unaltered over the area of deep tenderness that accompanies local pain.

(6) Local pain is not accompanied by that form of headache which is associated with tenderness of the scalp. Headache, if present, is a separate phenomenon, standing in no relation to the local pain and deep tenderness.

The organs of the body will be considered in the following order: Heart, p. 1139; Aorta, p. 1141; Lungs, p. 1141; Oesophagus, p. 1142; Stomach, p. 1142; Intestines, p. 1142; Liver, p. 1142; Kidney and Ureter, p. 1142; Bladder, p. 1143; Prostate, p. 1143; Testis, p. 1143; Epididymis, p. 1143; Ovary, p. 1143; Uterus, p. 1143.

1. Heart.—(a) Local Pain.

(1) *Due to Disease of Pericardium.*—When the pericardium is acutely inflamed the pain produced is in striking contrast to visceral reflected pain. For it is not accompanied by superficial tenderness; but over a greater or less extent of the pericardium the patient complains that percussion or pressure with the stethoscope in the intercostal spaces is painful. This deep tenderness does not transgress the limits

of the pericardium. In many cases this area of deep tenderness corresponds closely to the area over which pericardial friction is audible. Such is the condition not uncommonly found in a recent case of a first attack of pericarditis. Sometimes, however, this condition is complicated by the simultaneous appearance of referred pain and superficial tenderness due to the concomitant endocardial lesion (*vide infra*).

(2) *Due to Disease of Heart*.—Local pain is supposed to be commoner in cardiac diseases than reflected pain. Probably local pain is a distinct feature of the majority of painful cardiac states, but it is usually masked by co-existing reflected pain. But in some cases of cardiac failure when reflected pain is absent local pain is distinct. The patient complains of pain over the apex-beat that does not go through to the back and is increased by exertion. This form of pain is particularly marked in certain cases of mitral stenosis with an irregular beat, and in the form of senile heart that is accompanied by breathlessness and palpitation on exertion. The heart is said to feel as if it were 'bursting,' 'too big for the chest,' &c.

(b) *Reflected Pain*.

(1) *Due to Disease of Aortic Valves*.—True aortic stenosis throws more work on the wall of the left ventricle during systole. The ventricle therefore hypertrophies, compensation takes place, and the patient suffers from no symptoms. Not so aortic regurgitation. For here the ventricle empties itself during systole, but as soon as the wall relaxes at the beginning of the diastole the blood pours back from the aorta and distends its cavity. In true aortic stenosis the ventricle has to perform increased work during the systole, but is at rest during diastole. In pure regurgitation, on the other hand, there is not necessarily any increase in the work required during systole; but just at the moment when the wall is not toned to meet any effort the blood pours back into its cavity from the aorta. Now it is this distension at the moment when the walls of the cavity are at rest that is pernicious, and aortic regurgitation is of all cardiac disorders the

one most liable to lead to reflected pain. When both regurgitation and stenosis are present the condition is still worse. For not only has the systole to overcome a greater intra-ventricular resistance, but the diastole is broken by a rush of blood back from the aorta. The left ventricle hypertrophies to meet this increased resistance in front, but the increase in the force of the ventricular contraction will also increase the force with which the blood rushes back from the aorta at the beginning of the diastole. Thus reflected pain is more likely to be present with aortic regurgitation than stenosis, but most certainly when both lesions are combined. But pressure within the cavity of the ventricle during the diastolic period gives rise to a second evil. The ventricle never quite empties itself, but always remains somewhat distended, an ideal condition for the production of visceral reflected pain. In most cases this is a temporary condition, arising from some additional exertion in a heart working at the top of its power. In young people some excessive effort is necessary to produce this condition, but in older persons, and especially in those cases where the lesion of the aortic valves is caused by atheroma, it may arise after but slight exertion.

This permanent dilatation of the left ventricle cannot exist long or to any great extent without the mitral valve becoming incompetent. Directly this happens the pressure within the ventricle is relieved, for blood can now leave it by two channels. Thus, as soon as the mitral valve yields, the pressure within the left ventricle is relieved by a self-regulating mechanism, and reflected pain ceases. In the same way reflected pain is absent in those cases where mitral regurgitation arises synchronously with the lesion of the aortic valves.

Thus it will be seen that pain produced by aortic disease is due to the left ventricle. It is situated over the upper part of the chest, over the scapula, and down the inner side of the left arm. If severe and of long standing, it may cross to the right side in addition. In some cases it may become paroxysmal (*see below*). It is accompanied by more or less superficial tenderness over the second, third,

PLATE XIV.

The areas coloured Blue stand in relation both to organs of the head (e.g. the eye) and organs of the trunk (e.g. the stomach). Those coloured Red stand in direct connection only with organs of the head—

<i>Eye</i>	1. Cornea and Ant. Chamber	Frontonasal and Midorbital.
	2. Ciliary Region	Mainly Midorbital—also whole forehead if acute.
	3. Iris and Post. Chamber	Mainly Frontotemporal. Temporal and Maxillary.
<i>Teeth</i>	1. Upper Jaw	Incisors. Frontonasal. Canine. ? Nasolabial. 1st Bicuspid. Nasolabial. 2nd Bicuspid Temp. or Maxil. 1st Molar Maxil. 2nd and 3rd Molar Mandibular.
	2. Lower Jaw	Incisors, Canine, 1st Bicuspid. Mental, 2nd Bicuspid? 1st and 2nd Molar, Hyoid. 3rd Molar, Hyoid or Superior Laryngeal.
<i>Ear</i>	Middle ear	Hyoid.
	Internal Ear and Mastoid (with Tension only)	Vertical and Temporal.
<i>Tongue</i>	Mental, Hyoid, Laryngeal and Occipital.	Occipital.
<i>Tonsil</i>	Hyoid.	
<i>Nose</i>	Frontonasal and Midorbital (mainly).	

Area on the Scalp	Area on the Trunk	Organs in relation with these Areas

fourth, and fifth dorsal segments (*see* Plates X. and XII.).

(2) *Due to Disease of Mitral Valves.*—In cases of mitral incompetence a free path is open into the pulmonary circulation, and the pressure in the ventricle, therefore, always remains low. Cases of pure mitral incompetence are unattended by visceral referred pain. In a similar way in uncomplicated *mitral stenosis* no referred pain is produced. But suppose that, as soon as the auricular systole has expelled the blood through the narrowed mitral orifice, blood is again forced back into the auricle by the ventricular systole, the auricle will be distended at the moment when its walls are relaxing, and pain will result. Thus, where a systolic murmur is heard over the apex, accompanied by the short sharp first sound of stenosis, with or without a diastolic murmur, reflected pain and superficial tenderness are liable to make their appearance. In such cases it is the auricle which bears the brunt of the altered conditions, and the pain and tenderness lie over one or more of the fifth, sixth, seventh, eighth, and possibly ninth, dorsal areas.

(3) *Paroxysmal Pain of Cardiac Origin* (*see also* ANGINA PECTORIS).—Angina Pectoris is not a disease, but a convenient name for a group of symptoms that make their appearance in paroxysms. A typical attack of angina pectoris is made up of one or more of the following groups of symptoms: (1) A sense of faintness or impending death; the face seems to become cold and the jaws stiff, and a dead feeling to spread over the body. (2) A feeling of suffocation accompanied by local pain at the epigastrium or over the heart. (3) Radiating pains mostly over the upper part of the chest and in one or both arms. These pains follow the lines laid down in figs. 1 and 2, are accompanied or followed by superficial tenderness, and are thus of the true visceral reflected type. These symptoms are present to a different degree in individual cases. Thus in those cases where the arteries are degenerated but the heart is free from endocardial murmurs, the first and second symptoms are frequently present alone. Where, however, the degenerate arteries and myocardial signs are accompanied by aortic murmurs the third is usually added in marked form. In young persons with marked aortic regurgitation of rheumatic origin (unaccompanied by mitral regurgitation) attacks of paroxysmal cardiac pain consist almost exclusively of violent radiating pains of the reflected type unaccompanied by the first symptom, and usually by the second to a comparatively slight extent.

Thus we obtain the following rule: If the patient habitually suffers from reflected pain of cardiac origin the attack of angina pectoris will consist of a paroxysmal increase in the intensity and distribution of this pain. If, on the other hand, he is habitually free from visceral reflected pain the attack will more closely resemble sudden heart-failure, and will be accompanied by a feeling of faintness or impending death with more or less local pain at the epigastrium and over the area of the heart.

2. *Aorta.*—An aneurysm of the aorta may produce three forms of pain: (1) Local pain due to pressure on the vertebrae or ribs. This only occurs with aneurysms of considerable size. (2) Pain due to pressure on nerve-trunks which is referred to the peripheral distribution of the sensory fibres of those nerve-trunks, exactly as when the elbow is struck the pain is referred to the little finger. (3) Visceral reflected pain produced according to the general

laws laid down above, the aorta acting as a hollow organ. Visceral referred pain can only be produced so long as the aneurysm is, at any rate in part, contained within a wall composed of the tissues of the aorta. As soon as the aneurysm reaches such a size that its walls are mainly composed of connective tissue, visceral referred pain ceases owing to the destruction of the visceral nerves necessary for its production. Thus visceral referred pain is more commonly present in aneurysms of small size.

The position of the visceral referred pain and its accompanying superficial tenderness vary according to the position of the aneurysm. Thus the nearer the aneurysm lies to the aortic valves the more nearly the pain and tenderness resemble that produced by aortic regurgitation. If the aneurysm is situated at any part of the arch between the heart and the entry of the ductus arteriosus, the superficial tenderness may lie over the first, second, third, or fourth dorsal, or third and fourth cervical areas. Occasionally the areas on the front of the neck seem also to be affected. As soon, however, as the aneurysm invades that part of the aorta on the distal side of the entry of the ductus arteriosus these upper segmental areas are replaced by pain and tenderness over the fifth, sixth, and seventh dorsal areas. The lower the aneurysm on the dorsal aorta the lower the segment mainly affected. Thus aneurysms of the abdominal aorta may produce pain over the ninth, tenth, eleventh, twelfth dorsal, and first lumbar areas. Pain and tenderness over these areas may be extremely misleading. For if it lie over the twelfth dorsal or first lumbar area the patient will complain of pain over the extreme lower part of the lumbar spine, in the groins, and over the front of the thigh. Yet the swelling and pulsation will be felt at or above the umbilicus.

3. *Pain in Lung-Disease.*—(a) *Local Pain.*—Pain of this type occasionally appears in the neighbourhood of tubercular foci or large areas of pneumonic consolidation, but in most cases stands in definite relation to inflammation of the pleura. It is absent when the side is at rest, is intensified by inspiration, particularly by the long inspiration which follows a cough, a laugh, or a sneeze. The pain is said to be stabbing, but does not go through the chest from back to front as does referred visceral pain, and is localised to one area instead of being distributed over a band around the body. This pain is associated with deep tenderness to pressure or percussion in those intercostal spaces within which pleural friction can be heard. If the pleurisy is acute the intercostal trunks may become implicated in the inflammation, and pain appear over their terminal distribution exactly as pain appears in the little finger when the ulnar nerve is injured. Thus an acute pleurisy may cause pain over the abdomen or even the iliac fossa of the same side. This is not a visceral reflected pain, for it is only present over that portion of the nerve-trunk distal to the inflammatory lesion, and is not present over the back. It may occasionally be accompanied by superficial tenderness. But, unlike the superficial tenderness that is associated with true visceral reflected pain, the tenderness that may accompany a pleurisy is only present in front of (on the distal side of) the patch of pleural inflammation.

(b) *Visceral Reflected Pain.*—In order that reflected pain may appear it is necessary that the disease should not render the nerve-end organs in the lungs incapable of stimulation. Now in *acute*

lobar pneumonia the essential process of the disease is a consolidation of one or more lobes of the lung and complete obliteration of the alveoli by exudation. Thus the majority of cases of acute lobar pneumonia are unaccompanied by visceral reflected pain and superficial tenderness owing to the fact that the nerve-terminals are removed from the influence of internal pressure or external traction in consequence of consolidation of large areas of lung-tissue. In the same way if the lung has undergone *fibrotic changes* (as in the so-called fibroid phthisis) it is no longer capable of causing visceral referred pain. *Excavation of the lung*, by the destruction it produces, also renders the affected portion of the lung incapable of producing visceral referred pain, and thus those cases of pulmonary tuberculosis in which excavation forms the principal lesion may be painless. On the other hand, acute bronchitis may be accompanied by visceral reflected pain if the lung has not been altered by repeated previous attacks. In the same way visceral reflected pain accompanies those cases of pulmonary tuberculosis in which the disease advances by repeated bronchitic attacks, each of which leaves the lung more damaged than before. In such cases reflected pain and its accompanying superficial tenderness are frequently a marked feature in the progress of the disease.

The pain and tenderness of pulmonary disease occupy one or more of the following areas: Cervical, 3 and 4; dorsal, 3, 4, 5, 6, 7, 8, and 9. The nearer the disease to the apex of the lung, the more likely are cervical 3 and 4 to be represented in superficial tenderness, the nearer to the base the more certainly will the pain and tenderness lie over the mid-dorsal areas. Thus it is noticeable that disease of the base of the lung can cause pain and superficial tenderness over the three great gastric areas, the seventh, eighth, and ninth dorsal. If pain and tenderness over these areas is a marked feature of lung-disease the patient will suffer from secondary gastric symptoms (*vide* § 5).

4. **Œsophagus.**—As a rule there is not much referred pain in diseases of the œsophagus. But in a case of stricture of the lower part of the œsophagus pain and superficial tenderness may make their appearance over the fifth, sixth, or seventh dorsal areas after passage of a bougie.

5. **Stomach.**—In diseases of the stomach the seventh, eighth, and ninth dorsal areas are frequently mapped out by superficial tenderness to a greater or less extent. Sometimes the sixth dorsal makes its appearance in company with the seventh dorsal, and the tenth may appear with the ninth. Thus the whole supply of the stomach seems to lie between the sixth and tenth dorsal. In cases where pain is present after the ingestion of food, as in gastric ulcer, the higher the area of pain and tenderness, the sooner after food will the pain arise. Thus in those cases where the seventh dorsal segment is mainly affected and the maximum pain and tenderness is situated at and around the ensiform cartilage, the pain will come on within half an hour of taking food. On the other hand, when the ninth or tenth dorsal are mainly affected, the onset of pain may be deferred for an hour and a half. Thus it would seem that the cardiac end of the stomach stands in relation mainly with the sixth and seventh dorsal, the pyloric end mainly with the ninth and tenth dorsal areas.

6. **Intestine.**—(1) *From the Duodenum to the Sigmoid Flexure.*—The pain of intestinal affections

is frequently diffuse, ill-defined, and unaccompanied by tenderness of the skin. Thus lead-colic and many of the colicky pains that accompany an error of diet or summer-diarrhoea do not belong to the type of visceral reflected pains. Where melæna and pain in the abdomen are present, apparently due to ulcer of the duodenum, the pain may be of the reflected type and be accompanied by superficial tenderness over the tenth dorsal area. In the gastro-enteric attacks which sometimes follow chronic constipation or fecal impaction, visceral reflected pain and superficial tenderness may be present from the seventh to the eleventh or twelfth dorsal. In the same way a strangulated hernia may produce pain in the abdomen in the neighbourhood of the umbilicus with superficial tenderness within the tenth dorsal area. Acute diseases of the colon may cause visceral reflected pain and superficial tenderness over the tenth, eleventh, and twelfth dorsal areas. But chronic colitis is usually accompanied by local pain with deep tenderness over the affected part. Thus the intestine from the duodenum to the sigmoid flexure would appear to stand in relation to the tenth, eleventh, and twelfth dorsal segments.

(2) *The Rectum.*—Irritation of the rectum produces not only a local pain of an intense and sickening character, but also, occasionally, reflected visceral pain. This pain is situated over the buttocks and the upper part of the back of the thigh, and when severe is accompanied by superficial tenderness over the third and fourth sacral areas.

7. **Liver and Gall-Bladder.**—Any condition associated with inflammation of the capsule of the liver produces local pain, accompanied by deep tenderness on pressure. Thus, perihepatitis from whatever cause, and secondary malignant growths, are liable to be accompanied by deep tenderness.

Slow enlargements of the liver, and all forms of fibrosis, are unaccompanied by reflected pain. But when, in consequence of cardiac failure, the liver suddenly enlarges, for the first time the patient is liable to complain of pain in the right hypochondrium, right iliac fossa and right loin. This reflected pain may be accompanied by superficial tenderness over the ninth and tenth dorsal areas of the right side. Abscess of the liver, especially when multiple, may cause reflected pain over the eighth, ninth or tenth dorsal, and is also liable to be associated with pain over the right shoulder-joint, probably representing the fourth cervical area. In an attack of biliary colic the pain is of the visceral reflected type, and a paroxysm may be followed by widespread tenderness from the seventh to the tenth dorsal, not only on the right side, but also on the left half of the abdomen. Between the attacks, pain and tenderness are usually situated within the eighth and ninth dorsal of the right side.

Thus the liver seems to be associated with the seventh to the tenth dorsal on the right side, but more particularly with the eighth, ninth, and tenth. The gall-bladder seems to be principally associated with the eighth and ninth dorsal.

8. **Kidney and Ureter.**—Affections of the finer structures of the kidney, such as the various forms of nephritis, cause no reflected pain or tenderness. But all conditions that lead to interference with free outflow from the pelvis of the kidney are liable to be associated with this type of pain. During an attack of renal colic the pain may occupy the greater part of the abdomen and back, but is

usually greatest on the side of the affected kidney, and over the tenth, eleventh, and twelfth dorsal areas. After an attack the tenth, eleventh, and twelfth dorsal may be tender. If a stone passes, the pain may extend to the knee, and all the areas from the tenth dorsal to the second lumbar be tender. If a stone is fixed in the kidney it will cause no pain until the patient is exposed to some unusual jolting. Pain may then appear within the tenth dorsal area. Floating kidney and paroxysmal hydronephrosis may occasionally cause pain and tenderness over the tenth, eleventh and twelfth dorsal areas. Thus the kidney is particularly associated with the tenth dorsal, and also with the eleventh, and probably the twelfth dorsal. The ureter seems occasionally to cause pain as low as the second lumbar.

9. Bladder.—Irritation of the bladder, especially about the neck, is liable to cause pain over the buttocks and back of the thighs. An irritant applied to the mucous membrane, the passage of large clots of blood, and the presence of a calculus will all cause pain over the third and fourth sacral areas. Retention of urine and over-distension of the bladder can lead on rare occasions to radiating pains of the reflected type. These pains lie over the tenth and eleventh dorsal, but are rarely if ever associated with superficial tenderness.

10. Prostate.—Unless the disease is acute no pain is produced; but with acute prostatitis pain may be present down the back of the legs. Tenderness may be present over the second, third and fourth sacral, and occasionally even over the sole of the foot. Such cases are usually diagnosed as sciatica. Sometimes prostatitis seems to be accompanied by pain and tenderness over the tenth dorsal area. It is difficult to say if this is a primary or secondary manifestation, but if the former it is of interest in that it would represent the double origin of the prostate.

11. Testis.—The testicle is so rarely affected alone that it is difficult to be certain of the areas with which it is connected. Where, however, the organ has been crushed, and in a few cases of true orchitis, the patient may refer his pain to the abdomen and loin (dorsal 10).

12. Epididymis.—Acute epididymitis may be associated with reflected as well as local pain. In such cases superficial tenderness may be present over the maximum spots of the eleventh and twelfth dorsal. The tenderness rarely extends over the full areas.

13. Ovary.—‘Ovaritis’ is liable to be associated with widespread pain and tenderness (*vide* § 6). But occasionally, after examination, when the ovary is prolapsed and tender, superficial tenderness may be present over the tenth dorsal area. Moreover, it is not uncommon to find the tenth dorsal area alone the seat of pain and superficial tenderness, when there is reason to believe the ovary is affected. Thus the ovary, like the testis, appears to be mainly associated with the tenth dorsal.

14. The Uterus and its Appendages.—All abnormal states of the female genitalia are liable to lead to widespread reflected pain accompanied by superficial tenderness over the areas from the tenth dorsal to the second lumbar, and the first to the fourth sacral (*vide* § 6). But in cases where the pain is less generalised it is possible to lay down a few general rules. Thus certain cases of disease

of the Fallopian tubes produce pain and tenderness, situated mainly over the eleventh and twelfth dorsal, and first lumbar. Contractions of the uterus are liable to produce pains over areas from the eleventh dorsal to the second lumbar, while forcible dilatation of the os uteri is associated with pains over the sacral areas. The after-pains of labour may extend over both the lower dorso-lumbar and sacral groups, but where the os uteri has previously been extensively lacerated by a previous labour, the sacral pains may be absent. These pains, with their accompanying superficial tenderness of the abdomen, are frequently mistaken for those of peritonitis, from which they differ in that they are present in the loin, and over the sacrum and upper part of the thighs.

15. Eye.—In persons suffering from some error of refraction the headache is said to be ‘over the eyes,’ and when asked to point with two hands to the position of the headache, the patient places the tips of the fingers over the centre of each eyebrow. If we now pick up the skin gently between the finger and thumb, the patient winces as soon as we reach a spot about three-quarters of an inch (2 cm.) from the middle line on either side. If the blunt head of a pin is used he complains that he is tender, or that he is being pricked, as soon as an area over the centre of the eyebrow is reached. By either of these methods the headache produced by *hypermetropia* is found to be associated with superficial tenderness over more or less of the area the writer has called the mid-orbital (*vide* Plate). As a rule, in a pure case of hypermetropia the maximum only of this area is present, but occasionally, especially if the patient is seen immediately after reading or sewing, the whole area, including the patch on the front of the hairy scalp, may be tender. If due to hypermetropia the headache will be found to be worse over that eye in which the error of refraction is greatest. This headache has certain peculiar characteristics. It comes on in the morning as soon as the eyes are opened, is then most intense, and gradually wears off during the day if the patient does not engage in any near work. It is intensified or produced by reading and sewing. It disappears if the eye is put under atropine. Sometimes it is not easy to say whether a headache accompanied by mid-orbital tenderness is due to an error of refraction, which is undoubtedly present, or to some other cause. In such a case, before correcting a slight error of refraction, it is well to make sure of the following points: (1) The headache is definitely made worse by reading and sewing. (2) It comes on in the morning as soon as the eyes are opened. (3) It disappears under atropine applied for a sufficient length of time to paralyse accommodation. (4) There is absolutely no pain or tenderness elsewhere in the body, and, especially, no tenderness over those areas of the body which are definitely associated with the mid-orbital (*vide* 22). If, however, pain and tenderness are present elsewhere in the body, or if the patient is anæmic, it may be quite impossible to say whether the hypermetropia present is really the cause of the headache.

On the other hand, simple *myopia*, however high the error may be, causes no such headache and tenderness. The myope sometimes complains of a ‘tired, aching feeling’ over the forehead. This cannot be definitely localised, and is not accompanied by superficial tenderness of the forehead.

It is never present except after a long and tiring round of looking at objects at a distance (e.g. in a picture-gallery), and is always absent after a night's rest. There is, however, one condition in which simple myopia may produce a mid-orbital headache associated with tenderness—myopia associated with spasm of accommodation. This headache, like that produced by hypermetropia, entirely disappears under atropine. In progressive myopia the conditions are somewhat different. For in this disease destruction is progressing at the back of the eye. Patients suffering from this disease sometimes complain of 'pain on the top of the head,' and some tenderness of the hairy scalp is occasionally found in such cases. Such patients far more commonly complain of a pain 'at the back of the eye,' especially aggravated by movement of the eye. This pain is not associated with superficial tenderness, and appears in many cases to be a local, as opposed to a reflected, pain.

Myopic astigmatism, when uncomplicated, does not produce referred pain or tenderness. On the other hand, *hypermetropic astigmatism* is an even more fruitful source of headache and tenderness over the mid-orbital region than simple hypermetropia. Thus, whereas a simple error of $+1$ or $+2D$. can sometimes be neglected, an astigmatic error of $+1D$. will frequently produce the most definite pain and tenderness.

Anything which tends to produce a permanent abnormal tone of the ciliary muscle will produce referred pain. Thus unsuitable glasses may cause more headache and tenderness than the original error of refraction. This view is supported by the absence of referred pain and tenderness when presbyopia is fully established. A patient may have been hypermetropic, and have suffered from pain over the eyes all his life, without appreciating that he has an error of refraction. When the error manifests itself with the onset of presbyopia, his vision fails for near objects, but his headache improves. Thus headache may be present at forty but not at fifty.

Affections of the *conjunctiva* or of the outer layer of the cornea produce no referred pain. Injury to the surface-epithelium of the cornea produces an intense smarting pain, which is well defined and local. It is exactly equivalent to the well-known local pain produced by injuries to the conjunctiva. If, however, the deeper parts of the *cornea* be affected, as in deep and ragged ulcers of the cornea; or if the tension in the anterior chamber be increased, marked reflected pain may appear. The patient then complains of pain over the forehead; and more or less of the fronto-nasal area may be tender. As a rule, however, the maximum only of this area is present; for if the affection of the cornea is sufficiently grave to produce superficial tenderness over the whole fronto-nasal area, some part of the mid-orbital area will also be affected.

Should the substance of the *iris* be inflamed the pain is usually said to be 'on the temple' or 'in the cheek.' Corresponding to this pain superficial tenderness may be present over the fronto-temporal, maxillary, and temporal areas.

Should the tension in the vitreous chamber rise, as in *glaucoma*, the chief pain shifts further back, and is mainly referred to the temple. Thus in true glaucoma the pain may lie over the fronto-temporal, temporal, and maxillary areas, but the maximum pain is reflected into the temporal area. All

these areas may be more or less tender. The teeth of the upper jaw ache on the side affected. If the pain and tenderness spread forwards to affect the frontal area the teeth of the upper jaw ache up to the middle line; and if the pain and tenderness spread back behind the temporal area, as it not uncommonly does in an acute attack of glaucoma, the teeth of the lower jaw may also ache. Occasionally the teeth affected are tender to percussion, as though periodontitis were present. That this tenderness is reflex, and not due to any actual change in the sockets of the teeth, is shown by the daily variation, during the progress of a particular case, in the position and number of the tender teeth—a variation which seems to be related to the number and position of the areas which are tender on the surface of the head.

It is exceedingly difficult to determine what special areas, if any, are associated with disturbances of the retina and optic nerve. Detachment of the retina, if it occurs suddenly, is sometimes associated with tenderness over the vertical area, and pain 'over the top of the head.'

16. Teeth.—The first stage of caries of a tooth consists of removal of the enamel and excavation of the underlying dentine. During this process pain may or may not be present; but provided the dentine is affected, pain can mostly be elicited by stimulation. Now as long as the pulp cavity is not exposed, the pain remains local. The patient will complain of an aching tooth and will point to the one affected. If, however, the pulp-cavity is exposed, the pain alters in character and distribution. It starts in the affected tooth and shoots into the face, forehead, neck, or ear. Each stab of pain lasts a few moments, only to be followed more or less rapidly by a second twinge. This is the well-known 'neuralgia' caused by affections of the teeth.

On testing the face or neck during this 'neuralgia' some one or more of the areas described will be tender. On the face this tenderness is superficial, but, as pointed out above, parts of the jaw, mouth or tongue may be tender at a distance from the affected tooth, owing to their intimate connection with the distribution of these areas. Thus teeth at a distance from that affected may ache and be tender to the touch.

After caries has reached the pulp-cavity many different changes can occur. The pulp and nerve may become inflamed and reddened, and die rapidly and steadily. But sometimes this death takes place much more slowly. One part of the whole of the pulp in the chamber may die, and with it the nerve in one or more roots, and yet the nerve in one root may remain alive and potent for harm for a long while: or the inflammation and death of the pulp may go on slowly under a cap of sodden dentine. If the pulp becomes fibrous or calcareous, it no longer causes referred pain. But such cases are frequently deceptive; for although the nerve in one root may pull out like a thread of cotton, it is not uncommon to find that another root contains a small vestige of living pulp. Irregular calcification with the formation of pulp-stones frequently leaves some living pulp, and is a frequent cause of referred pain. The condition known as 'polypus of the pulp' is frequently associated with a living nerve. The writer has an impression that where the polypoid formation is large the nerve is likely to be dead; where, on the other hand, the fungating portion is small, the nerve will probably be alive. The point

of the probe will settle this at once. For should the nerve be alive the least touch with the point on the protruding granulation-tissue will cause exquisite pain. These cases show well marked superficial tenderness of the face.

When the pulp and nerve are dead the tooth may still be a source of pain, owing to inflammation of the periodontal membrane or abscess about the tooth. But this pain, in the vast majority of instances, is local and not referred. Sometimes pressure on a tooth in this condition is said to cause 'darting' pain which travels beyond the limits of the tooth. Thus, on pressing a lower bicuspid, which seemed to the patient to be longer than its neighbours, the pain was said to 'run along the jaw.' In the same way pressure on an upper canine produced pain darting up in the line of the socket. Such pain is rarely accompanied by superficial tenderness, and seems to follow a peripheral rather than a central distribution.

The exact innervation of each tooth seems to vary somewhat, but the following table gives the approximate relationship in which the various teeth stand to the areas on fig. 5:—

UPPER JAW.		LOWER JAW.	
Incisors .	Fronto-nasal.	Incisors .	Mental.
Canine .	? Nasolabial.	Canine .	"
1st Bicuspid	Nasolabial.	1st Bicuspid	"
2nd Bicuspid	Temporal or	2nd Bicuspid	?
	Maxillary.	1st Molar	Hyoid.
1st Molar .	Maxillary.	2nd Molar .	"
2nd Molar .	Mandibular.		
3rd Molar .	"	3rd Molar .	{ Hyoid or Superior Laryngeal.

17. Ear.—The pain produced by lesions of the auditory meatus, from its opening to the membrana tympani, is local, although frequently severe. If, however, the membrana tympani or middle ear be affected the pain will be referred to some point at a distance from the source of irritation and may be accompanied by superficial tenderness. When the membrana tympani is affected the middle ear is generally diseased. But in some cases where an accumulation of cerumen in the meatus is decomposing, the membrane is found to be reddened and inflamed. In many cases this redness will subside after removal of the plug, and there is no reason to suppose that the middle ear is affected. Some cases of this kind suffer from pain 'in the ear and under the jaw,' and occasionally superficial tenderness is present over the hyoid area. During suppuration in the middle ear before perforation of the membrana tympani occurs, the pain is intense. In hospital practice patients mostly wait until the membrana tympani is perforated, and the pain has somewhat abated, before finding their way to the ear-department. Thus it is extremely rare to see an adult in this condition. The history given by such patients points to the presence of pain 'at the top of the head' and 'in and behind the ear.' The pain on the top of the head abates when the discharge appears, but the pain 'behind the ear' remains. Occasionally, however, the orifice, once established, becomes blocked. If this should occur the patient begins to suffer from pain on the top of the head, and in such cases the writer has seen superficial tenderness over the vertical and parietal areas of the scalp.

18. Tongue.—It is a well-known fact in surgery that malignant disease of the tongue may cause pain in the ear or over the back of the head, in addition to the local pain in the tongue itself.

If the disease involves the *anterior part* of the tongue, pain is complained of over a spot close to the point where the mental nerve rises through the deeper structures of the jaw to supply the skin. This is the maximum spot of the mental area. This pain in the front of the lower jaw is sometimes associated with superficial tenderness over the mental area. If the *lateral part* only of the tongue is implicated the patient complains of pain 'in the ear,' and behind the ramus of the lower jaw on the side affected. In such cases the hyoid area is not uncommonly found to be tender. If the lesion is situated on the *dorsum* of the tongue behind a line about 3 to 4 cm. from the tip, the pain is 'in the throat' close to the cornu of the hyoid bone. It may also be felt in the back of the head in addition. Occasionally tenderness is present, more commonly in the territory of the superior laryngeal, more rarely in that of the occipital area.

19. Tonsil.—When the tonsils are affected pain appears in the ear, and behind the angle of the jaw (Hyoid area). If the disease is acute and associated with a rise of temperature, wide-spread pain and tenderness may result (*vide* § 6).

20. Nose.—But few nasal affections are painful; and even in those that cause pain, the pain is but rarely acute.

In inflammatory conditions of the olfactory portion of the nose above the middle turbinate bones, pain associated with slight superficial tenderness may appear over the fronto-nasal or mid-orbital areas of the forehead. Inflammation of that part of the nose associated with the lacrymal duct, so common in eye-practice, occasionally leads to mid-orbital headache and tenderness.

21. Larynx.—Affections of the larynx, though producing much discomfort and local pain, do not in the majority of cases produce referred pain and tenderness. The inflammatory conditions, apart from syphilis and tuberculosis, cause great local soreness, but as a rule the soreness is definitely in the larynx.

But where the larynx is in process of destruction by tuberculosis, the pain is not only local, but referred, and superficial tenderness may be present over one or both of the areas called by the writer the superior and inferior laryngeal. When the upper of these areas is tender, the pain is situated a little anteriorly to the cornu of the hyoid bone; when the lower area is affected the pain lies just in front of the anterior border of the sterno-mastoid muscle at about the horizontal level of the cricoid cartilage.

Pain in the Head secondary to disease of organs in the Thorax and Abdomen.

Any organ of the chest and abdomen may, under favourable conditions, cause reflected pain in the head accompanied by tenderness over the areas of the scalp coloured blue (Plate XIV.). The degree to which these pains in the head attract the patient's attention varies greatly. Sometimes he is unaware that the scalp is tender, or he may be aware of the soreness but complain of no pain unless the part be touched. The more acute the pain and tenderness on the body, the more intense will be the pain and soreness of the scalp.

An area on the scalp does not stand in direct primary relation with any organ in the chest or abdomen, but is associated with the segmental areas of the trunk as low as the tenth dorsal. The lower the segment on the trunk that is affected, the more

posterior will be the tender area on the scalp; the higher on the trunk the more certainly will the pain and tenderness be found over the forehead. Thus the third and fourth cervical and the second, third, and fourth dorsal seem to be associated with pain and tenderness over the forehead (fronto-nasal and mid-orbital); the fifth and sixth dorsal with the fronto-temporal; the seventh dorsal with the temporal; the eighth dorsal with the vertical; the ninth dorsal with the parietal; and the tenth dorsal with the occipital areas.

Below the tenth dorsal the segmental areas stand in no relation to those of the scalp. Thus, speaking broadly, it is quite immaterial for the production of temporal headache with tenderness over the temporal area of the scalp, whether the disease be some gastric disturbance, phthisis destroying the base of the lung, or a certain form of mitral disease. The only necessary condition is that one of these diseases should produce pain and tenderness within the seventh dorsal area, when the temporal area will appear tender irrespective of the nature of the diseased organ.

§ 4. Pain produced by Inflammation of Serous Cavities (Pericarditis, Pleurisy, and Peritonitis).

Inflammation of the pericardium, pleura, or peritoneum causes no reflected pain or superficial tenderness of the visceral type. As has been pointed out above (§ 3, 1a and 3a) for the pericardium and pleura, so also with inflammation of the peritoneum local pain makes its appearance accompanied by tenderness on deep pressure or percussion over the affected part. No tenderness is present in the back or at any part where manipulation does not directly affect the inflamed serous cavity. (For the explanation of pain in the abdomen with pleurisy, *vide* 3a, p. 1141.) Thus such tenderness on deep pressure becomes of direct localising value. In the pleura and pericardium the area of deep tenderness corresponds roughly with the area over which friction can be heard. In the peritoneum it corresponds fairly accurately with the area of inflammation found *post mortem* or at an operation for relief of the disease. The absence of superficial tenderness of the visceral type and the presence of well-marked local tenderness are important diagnostic differences between the pain produced by inflammation of the lining of a serous cavity and that caused by disturbance within an organ it contains.

§ 5. Sympathy and Association.

When an organ becomes diseased in such a way that visceral reflected pain is produced, any other organ that receives its sensory supply from the same segment will become tender. Hence during the pain produced by renal calculus the testicle of the same side becomes tender, for both kidney and testicle are supplied mainly from the tenth dorsal segment.

Disease of the lower lobe of the lung tends to produce pain over the seventh, eighth, and ninth dorsal areas. But these are the areas that stand in peculiar relation to the stomach; hence in such cases the stomach tends to become hyperæsthetic, and the patient complains of pain after food, with nausea and, occasionally, vomiting. This is the origin of one form of reflex dyspepsia, occurring in pulmonary tuberculosis, that disappears with the subsidence of the signs of lung-disease. A similar reflex dyspepsia may arise in mitral disease if it is

accompanied by pain and tenderness over the seventh, eighth, and ninth dorsal areas (*vide* § 3, 1b).

Certain organs that are not supplied by the same segment seem to be naturally related to one another. This is the case with the uterus and the breast. Thus within twelve hours after labour it is not uncommon to find a woman suffering from a pain under the heart associated with cutaneous tenderness which comes and goes with the 'after pains.'

§ 6. Conditions which lead to widespread Superficial Tenderness.—So far it has been assumed that a disturbance of each particular organ leads to pain and tenderness over certain areas, and over those areas only. But under the following conditions the pain may spread widely.

If the pain suddenly increases in intensity it is liable to become bilateral. Thus in gall-stone colic more or less tenderness appears over the seventh, eighth, and ninth dorsal areas on the left side, as well as on the right. In the same way the pain and tenderness produced by a calculus in one kidney may spread to the other side at the same spinal level. But in all such cases the pain and tenderness are most marked, appear first and disappear later on the side of the diseased organ.

If the pain assumes a paroxysmal character it may spread widely in all directions, and be followed by extensive superficial tenderness. In renal and gall-stone colic, and in paroxysmal cardiac attacks, the pain of the attack, and superficial tenderness that follows it, may extend beyond the usual renal, hepatic, or cardiac limits. After the attack both pain and tenderness settle down to the usual areas of the particular organ affected.

Then again any condition which decreases the resistance of the nervous system, or relaxes the control of the higher centres, will cause widespread visceral reflected pain.

If a patient suffering from anæmia has a carious tooth, that causes pain and tenderness of the reflected type, the tenderness will be found to spread widely, and may affect the whole or one half of the face and neck, or even spread to the arm of the same side. In such a patient, hypermetropia may cause universal tenderness of the scalp, and a trifling gastric or gastro-intestinal disturbance, pain and tenderness over the greater part of the trunk. Anæmia and chlorosis as such are not necessarily accompanied by headache or gastralgia; but directly a small focus of visceral reflected pain arises in those who are anæmic or chlorotic, the pain and tenderness spread out of all proportion to their primal cause. Moreover, if the cause of the primary focus is removed (e.g. by extracting the diseased tooth) the pain does not cease, at any rate, immediately. For the resistance of the central nervous system being once broken down is with difficulty recovered.

The cachexia caused by wasting diseases may also lead to widespread tenderness, and is probably the cause of the widespread pain and tenderness of the reflected type that accompanies some cases of pulmonary tuberculosis.

A sudden rise of temperature will produce the same effect. Follicular tonsillitis, or any parenchymatous affection of the tonsils, is associated with cutaneous tenderness, extending round the neck from the lower part of the mastoid behind, almost to the middle line of the neck, just above the *pomum Adami*. If one tonsil only is affected one

side of the neck alone is tender over this area. But let the onset be sudden and associated with a rise of temperature to 101° or 102° F. We shall now find the same zone of tenderness, but in addition there will be pain and tenderness over the forehead, in the occipital region, over the maximum of the tenth dorsal area in the back, and at the epigastrium (representing the seventh dorsal), and probably also at several other points in the body and limbs, all of which represent the maxima of their various segmental areas. Thus a rise of temperature has added, to a simple area of tenderness representing the organ primarily affected, a multiplicity of painful and tender spots, representing areas which could in no way be affected by the local manifestation of the disease. In some cases a sudden rise of temperature will produce this widespread tenderness without our being able to recognise any area of primary disturbance. This condition is produced most easily by true epidemic influenza. In this disease the patient notoriously complains of 'pains all over,' and careful examination shows that these pains are associated with tenderness in the skin. But influenza is not the only specific disease which produces these tender areas; they are sometimes present in typhoid fever. Such a condition is, however, uncommon, for the temperature, as a rule, does not run up rapidly enough to produce this widespread tenderness. The more usual condition of a patient suffering from typhoid fever in the first week is a very variable amount of tenderness over some part of the areas occupied by the seventh, eighth, ninth, and tenth dorsal.

In acute rheumatism in the very early stages before the joints begin to swell definitely, similar cutaneous tenderness may appear, though seldom, and always to a less extent than in the diseases before mentioned.

The diminution in resistance that is associated with menstruation is also a potent cause of spreading; for during menstruation trivial causes may lead to widespread pain and tenderness. If the patient has some affection of the cervical canal, such as chronic catarrh or polypi, she may be entirely free from pain until the flow comes on, when she will develop pain and tenderness over one or more of the following areas: tenth, eleventh, twelfth dorsal; first and second lumbar; fourth, third, and second sacral. Most of these areas may be affected, but even at the height of the disturbance the tenderness does not transgress the limits of the areas in connection with the pelvic viscera. Moreover, the areas corresponding to the part which is chronically diseased are always most affected. In other cases of dysmenorrhœa the patient may have suffered from pain and tenderness over a restricted area in the intermenstrual period. As soon as menstruation begins, pain and tenderness spread widely, until at last the whole trunk below the umbilicus, and the whole leg, including even the areas of the gap, may be tender.

Again, as was pointed out above (p. 1143), a normal labour is frequently followed by some pain and cutaneous tenderness. But the pain and tenderness very rarely overstep the areas associated with the pelvic viscera. But after abortion 'spreading' is very common, and although the course of the puerperium may be normal, the patient will frequently complain of pain and tenderness elsewhere than over areas representing the pelvic viscera. It would appear as if the resistance of the nervous system were increased *pari passu* with the progress

of normal pregnancy to bear the strain of normal labour; but that when abortion takes place it is unprepared for the strain put upon it, and generalisation takes place readily.

This breakdown of resistance and spread of pain and tenderness may also be produced by mental causes, or may be due to some inherent defect in the nervous system of the individual. Thus the so-called 'neurotic' individual is noticeable for the ease with which a slight visceral cause produces widespread pain and tenderness, and patients suffering from neurasthenia are particularly liable to widespread visceral pain.

HENRY HEAD.

PAINTER'S COLIC.—SYNON.: *Colica Pictorum*; Lead-Colic; Fr. *Colique des Peintres*; Ger. *Malerkolik*.—A form of intestinal colic, due to plumbism. See COLIC; LEAD, Poisoning by; and OCCUPATION-DISEASES.

PALATE, Paralysis of.—The chief causes of paralysis of the palate are diphtheria (see PARALYSIS, Diphtheritic); degeneration of the nuclei of the medulla oblongata (see LABIO-GLOSSO-LARYNGEAL PARALYSIS); growths in the basis cranii; and compression or inflammation of the nerves of the medulla. The first two causes usually lead to bilateral paralysis. Unilateral paralysis is commonly due to one of the last two causes. It is not caused by disease; the chief nerve-supply to the palate is from the spinal accessory, as clinical observation and experiments alike have proved.

SYMPTOMS.—In *bilateral* paralysis the palate hangs flaccid, and irritation of the mucous membrane excites no reflex movements. It is not raised in breathing or phonation: a convenient test is to make the patient utter the sound 'ah' in a high tone; the central palate should be raised by the levators. Deglutition is interfered with, the soft palate being no longer raised so as to shut off the posterior nares; and liquids are forced up into the nose by the contraction of the pharyngeal muscles. Speech is also affected: the resonance of the nasal chambers gives to it the 'twang' which only the *n* and *ng* sounds should possess. The explosive consonants cannot be well pronounced, because the open passage through the nose prevents the air being sufficiently compressed to give the sudden sound when the passage between the lips is open. Hence *p* and *b* become *f* and *v* respectively.

Unilateral paralysis of the palate causes little interference with deglutition. The chief muscles which raise the palate meet, it will be remembered, in the middle line of the soft palate, and for this reason one muscle is able to effect sufficient elevation of the whole palate to prevent the regurgitation of liquids. The voice may have a slight nasal twang, but the articulation of the labial explosives is not interfered with. When at rest, the paralysed half may or may not be a little lower than the other. The uvula is said to be oblique, inclined towards the opposite side, but this is doubtful; it is often straight in the middle line. A change in form when the azygos contracts may be expected, but is not always to be observed. The chief indication of the paralysis is the unequal elevation, which is recognised during the utterance of the sound 'ah.' It is the middle of the soft palate, just above the uvula, on which the elevators act, and when the muscular contraction is confined to one side, the base of the uvula is drawn a little towards the non-

paralysed side, and a dimple forms above the base of the uvula on that side only. This is the great sign of one-sided palsy. By faradisation a difference in the contractility of the muscles may be recognised, but the difficulties of the test preclude its general utility. Unilateral paralysis of the palate is often associated with that of the vocal cord on the same side, and often with paralysis of the same side of the tongue. This combination is met with especially when there is disease of the nerves at the side of the medulla. The paralysis of the tongue is, of course, due to disease of the roots of the hypoglossal; that of the vocal cord and palate to damage to the higher roots of the spinal accessory nerve.

DIAGNOSIS.—The recognition of bilateral paralysis of the palate depends on its immobility on voluntary effort and reflex stimulation; that of unilateral paralysis on the inequality of movement in the utterance of certain sounds. Difficulty in diagnosis is due to the frequent natural inequality of the arches, and obliquity of the uvula. The latter is so common under normal conditions, that no weight can be attached to it as an indication of paralysis. The opinion that the palate is sometimes paralysed in facial paralysis rests apparently upon the uvula being found to be oblique, and observers have been strangely puzzled by the frequency with which the uvula deviates to, as well as from, the paralysed side, and have formed various ingenious theories to account for the relation; the deviation is, in reality, a 'natural abnormality,' and has no connection with the facial paralysis.

PROGNOSIS AND TREATMENT.—The prognosis and treatment of paralysis of the palate are those of its causes. Locally the muscles may be galvanised by a long electrode, insulated except at its extremity, and furnished with a contact key, so that the circuit is not completed until the instrument is in position. The difficulty of applying electricity for any length of time, and the central nature of its common cause, make its practical value almost imperceptible. Food that is semi-solid is usually swallowed better than liquids; the measures desirable in general management are described under LABIO-GLOSSO-LARYNGEAL PARALYSIS.

W. R. GOWERS.

PALATE AND TONSILS, Diseases of.—*See* TONSILS; and UVULA.

PALERMO, in Sicily.—Moist, warm, equable. No sudden atmospheric changes in winter; the mean temperature being 55° F. *See* CLIMATE, Treatment of Disease by.

PALLIATIVE (*pallium*, a cover).—A term used in connection with the treatment of disease, when it is directed merely to the relief or mitigation of symptoms.

PALLOR (Lat.).—**SYNON.**: Fr. *Pâleur*; Ger. *Blässe*.

This term signifies whiteness or absence of colour. It is due to lack of blood in the affected part, whether due to contraction of the blood-vessels, diminution in the quantity of blood generally, reduction in the number of red-corpuscles, or relative deficiency of hæmoglobin in the individual corpuscles. *See* ANÆMIA; and CHLOROSIS.

PALPATION (*palpo*, I handle gently).—A method of physical examination, in which the hands are employed to appreciate certain conditions perceptible by the sense of touch. *See* PHYSICAL EXAMINATION.

PALPITATION (*palpito*, I beat or throb).—*See* HEART, Functional Disorders of.

PALSY.—A popular synonym for motor paralysis.

PALSY, SHAKING.—A synonym for paralysis agitans. *See* PARALYSIS AGITANS.

PALUDAL
PALUSTRAL } (*palus*, a marsh).—Of or belonging to a marsh. A term generally used in connection with malarial or marsh-fevers, on account of their frequent ætiological association with marshes. *See* MALARIAL DISEASE.

PANCREAS, Diseases of.—**SYNON.**: Fr. *Maladies du Pancréas*; Ger. *Erkrankungen des Pankreas*; *Krankheiten der Bauchspeicheldrüse*.

The diseases of the pancreas will be considered in the following order: 1. Anomalies; 2. General Pathology; 3. Hæmorrhage; 4. Pancreatitis; 5. Pancreatic Cysts; 6. Pancreatic Diabetes; 7. Tumours; 8. Tuberculosis; 9. Syphilis; 10. Pancreatic Concretions, *see* p. 334.

1. **Anomalies** of the pancreas are relatively infrequent and affect the gland itself as well as neighbouring organs, in which accessory pancreatic tissue has been found. In connection with the gland itself may be mentioned—separation of groups of lobules of the head-extremity and their displacement behind the mesenteric artery and vein; still larger islands of pancreatic tissue may be found fully separated and provided with an independent canal emptying into the main pancreatic duct; the tail-extremity may also become completely separated from the body except for the persistence of the duct of Wirsung; the descending portion of the duodenum may be surrounded by a ring of pancreatic tissue. Accessory pancreatic tissue has been found in the stomach, both in the greater and lesser curvature, between the serosa and muscularis and within the submucosa; in the duodenum and jejunum, external to the serosa and beneath the serosa; and in the wall of the ileum. Diverticula of the intestine have been ascribed to these displacements. Variations affecting the ducts also occur. The accessory duct (of Santorini) may be absent; the main duct may have two openings, side by side upon the plica longitudinalis of the duodenum, the bile-duct also having a separate orifice; four orifices are occasionally found, the highest being the accessory duct, the second the common bile-duct, the third the duct of Wirsung, and the fourth a supernumerary duct originating in the head of the pancreas. Again, there may be but one duct opening upon the papilla minor; in this case the ductus choledochus empties alone into the diverticulum of Vater; or with a normal number of ducts, the duct of Wirsung empties into the terminal portion of the bile-duct and the papilla major is wanting. Finally, on account of displacement of the pancreas upward, the pancreatic duct may empty into the stomach.

2. **General Pathology and Symptomatology.**—In an organ in which the physiological functions have been so carefully studied as the pancreas,

disturbance of these might be reasonably expected to lead to constant and characteristic symptoms at once recognisable. The contrary is, however, true. The reasons for this discrepancy are found in the fact that so far, at least, as the digestive juices of the gland are concerned, other organs can easily act vicariously. Thus the proteolytic action can be supplied by the gastric juice; the amylolytic by the salivary secretion; the fat-emulsifying by the bile, and both the latter in part by the intestinal juices; while certain micro-organisms present in the lower intestine are even capable of splitting the fat into glycerine and fatty acids. So far as we know at present, no other organ can supply the internal secretion; but experience has shown that a considerable part of the pancreas may be destroyed without leading to consequences such as might be expected to follow failure or deficiency of that hypothetical material. Moreover, the anatomy of the gland permits grave alterations in structure without producing corresponding symptoms. The presence of two excretory ducts, one of which can take over the entire work in default of the other, is a great safeguard, constituting a favourable anatomical condition as compared with that existing in the liver.

Pancreatic disease is not infrequently associated with morbid conditions in the neighbouring organs, the latter often obscuring the symptoms referable to the pancreas alone. Pathological processes, beginning in the intestine and stomach, may extend to the pancreas, this being especially true of malignant tumours and ulcerations; while inflammations of the bile-duct may involve the pancreatic duct and gland, and these structures may suffer in consequence of the impaction of gall-stones in the diverticulum of Vater. On the other hand, diseases beginning in the pancreas may lead to disturbances in other organs, especially the duodenum and liver, as in tumours of the head of the pancreas, which may erode the intestine, and soon compress and obstruct the common bile-duct. Hæmorrhage and inflammation, moreover, rarely remain limited to the pancreas; neighbouring organs are commonly invaded, and the general peritoneum is not infrequently involved. The symptomatology, therefore, may suggest morbid changes, not in the pancreas, in which the disease has started, but in some secondarily affected organ; or, again, the reverse may be true.

3. Hæmorrhage.—Hæmorrhages of the pancreas are not very infrequent. The punctiform varieties occur in the course of passive congestion in chronic diseases affecting primarily the heart, liver, kidneys, and lungs. Somewhat larger ecchymoses are met with in certain diathetic, infectious, and toxic conditions, as in scurvy, purpura, septicæmia, eclampsia, and phosphorus poisoning. More abundant hæmorrhages are associated chiefly with inflammations and necroses of the gland. The blood may appear in the interstitial tissue or within the acini; more commonly in the former location. The corpuscles may be recognisable as such, or different stages of pigmentary transformation may be found. Experiments upon the pancreas in animals have demonstrated that hæmorrhage is readily excited.

ÆTIOLOGY.—Hæmorrhage of the pancreas is recognised as a cause of sudden death; though the importance of the local lesion is still open to doubt. In some cases even copious bleeding into the pancreas may be of only minor importance, the condition being associated with similar hæmorrhages

in other organs, and resulting chiefly from disturbances of the circulation. Injection of relatively large quantities of blood into the pancreas in the dog sets up a sclerosis only of the organ (Flexner and Pearce).

The cause of the hæmorrhage can be established only in a certain proportion of the cases. The most frequent concomitant pathological condition is vascular disease, such as fatty degeneration, arterio-sclerosis, and lesions secondary to alcoholism and syphilis (Seitz). Fitz regards the anatomical relations of the blood-vessels as favouring hæmorrhage, the abrupt division of the larger branches of the arteries into vessels of small calibre, the height of the aortic pressure, and the variations in blood-content, as determined by the work of the diaphragm and abdominal muscles, all contributing to the production of rupture of their walls. Not infrequently hæmorrhage has been observed in cases in which adipose tissue has been present in the pancreas and the glandular cells have suffered fatty degeneration. Such a hæmorrhage may be the direct cause of death. The hæmorrhage has also been ascribed to fat-necrosis (*see below*). Both in human and experimental necrosis, when fresh, a zone of hæmorrhage, usually not exceeding a line in extent, surrounds the dead area; but inasmuch as such fat-necroses are frequently present in the absence of hæmorrhage, and constantly accompany inflammatory lesions of the pancreas, which themselves are often associated with hæmorrhage, their causal relationship to the bleeding is very doubtful. Hæmorrhage may also take place into cysts, in which case, as a rule, the gland is not implicated (*see ABDOMINAL CYSTS*). Furthermore, a few instances of severe and fatal hæmorrhages from malignant tumours of the pancreas have been recorded. Embolism and thrombosis of the pancreatic arteries are occasionally the causes; traumatism is a more frequent and a not unimportant ætiological factor, while inflammations are among the most common.

MORBID ANATOMY.—The pancreas in this condition displays a picture varying according to the degree and the age of the hæmorrhage. The gland is mottled and presents a predominating dark red or violet colour, due to the presence of blood, chiefly within the interlobular connective tissue. The glandular acini are distinguished as greyish, opaque foci scattered over the surface. The whole organ is swollen; the blood often infiltrates the periglandular tissue, or may collect in the lesser omentum. Upon microscopical examination, blood-corpuscles in great number are found within the interstitial tissue, often pressing the fibres apart, and extending into the glandular acini. The acini may preserve their form, or the cells be disturbed and their arrangement altered; the ducts sometimes contain blood. If the hæmorrhage is older, blood-pigment is found in the interstitial tissue, while the latter may also show an increase in its connective tissue.

When the bleeding is extensive, the entire tissue of the gland is destroyed and the blood invades the retro-peritoneal tissue. In other instances, the peritoneal covering is broken and the blood fills the lesser sac.

SYMPTOMS.—Slight bleeding is not associated with any recognisable symptoms; extensive hæmorrhages may arise during the best of health, and lead quickly to a fatal issue. A host of indefinite

symptoms, such as obstinate constipation, chronic dyspepsia, and colicky pains have been noted as preceding the onset of hæmorrhage. Just prior to a fatal attack severe pain of a colicky character in the upper part of the abdomen is complained of, and endures until the end. Almost from the first it is accompanied by nausea and vomiting, the latter, no matter how frequent and severe, giving no relief. The vomit is usually bile-stained; rarely it consists of a yellowish-brown fluid, or becomes bloody (Hooper). The abdomen is distended; only with extreme rarity does palpation disclose a tumour. In the rapidly progressing cases fever is rarely present; in the stage of collapse, subnormal temperatures are met with. The pulse, as a rule, is weak and quickened; loss of consciousness or delirium is but rarely noted. Not many careful studies of the urine are on record. In the 'lightning cases' it has either shown nothing abnormal or anuria has existed. Albumen has been found, and also sugar; the proportion of the latter having reached 6·1 per cent. in one of Cutler's cases.

TREATMENT.—Therapeutic measures are of little avail. It has been suggested to open the abdomen, expose the pancreas, and relieve the tension, since the fatal result is often due to pressure upon the solar plexus rather than to loss of blood. In the acutely progressive cases the procedure would rarely be resorted to, whereas in the more chronic types, especially where cysts and perhaps abscesses have developed, the surgeon may be able to do a great deal.

4. **Pancreatitis.**—Inflammations of the pancreas are not very infrequent occurrences. Excluding cloudy swelling, or so-called acute parenchymatous pancreatitis, which may occur in all severe infections and intoxications, we can distinguish several well-defined types of inflammation of the pancreas. These may profitably be considered under the headings, acute hæmorrhagic, suppurative, necrotic, gangrenous, and chronic indurative pancreatitis. Moreover, while the several varieties mentioned may have an independent existence, mixed forms may also exist.

(1) *Acute Hæmorrhagic Pancreatitis.*—This form of inflammation has not been sharply separated from pancreatic hæmorrhage. Indeed there is still much difference of opinion as to the occurrence of a well-defined pancreatic disease in which the inflammation is followed by extensive hæmorrhages. The free escape of blood into the gland, if it fails to produce immediate death, is followed by changes of an inflammatory nature in the organ. The majority of writers, however, adhere to the belief in a hæmorrhagic inflammation of the pancreas. Diffuse inflammations of the organ, in which hæmorrhage is either absent or inconspicuous, also occur.

Hæmorrhagic inflammations can also be produced experimentally. Allusion has been made to the readiness with which extravasations occur in the pancreas, and hence even mild operative procedures such as ligaturing and slight crushing of the gland may produce fairly extensive hæmorrhages. The introduction of irritating substances (e.g. artificial gastric juice, bile, caustic alkalis, bacterial cultures) into the pancreas through its ducts brings about a similar change even more strikingly. That the hæmorrhage in the last instance is not primary is shown by the histology of the lesions, for when death has taken place within twelve or fourteen

hours after the operation, great congestion of the vessels will be evident, the number of white cells in the blood will be increased, necroses in the gland will already have formed, and emigration of leucocytes taken place.

A large portion of the cases occur in male adults. Among the 41 instances collected by Körte only four were in women: McPhedran has reported one in a child nine months old.

ETIOLOGY.—The ætiology of the disease is obscure. Some, but not all, of the patients who have succumbed to it have been addicted to alcohol. In several cases cholelithiasis has co-existed (A. Mayo Robson, &c.). In these cases occlusion of the pancreatic duct at its orifice from pressure of a stone lodged in the diverticulum of Vater, by causing a damming-back of the secretions may possibly predispose to bacterial invasion.

The bacteriological study of human cases of this form of pancreatitis has given very inconstant and inconclusive results. By injecting the *B. pyocyaneus* and *B. diphtherie* into the pancreatic duct, the writer obtained intensely hæmorrhagic inflammation of the gland in several instances within forty-eight hours. The absence of demonstrable bacterial invasion in many cases indicates other modes of causation. The writer caused rapidly fatal hæmorrhagic pancreatitis in the dog, associated with peritoneal and pericardial fat-necrosis, by injections of artificial gastric juice into the duct of Wirsung; and Opie has produced a similar condition in the dog by injections of sterile bile into the duct.

MORBID ANATOMY.—The pancreas is found enlarged, and the interstitial and even the glandular tissues are infiltrated with blood. Clots of a considerable size may occur in the interlobular tissue and upon the surface of the organ; or instead of blood, a fibrinous exudate may be found upon the capsule. On section, the gland exhibits, besides a hæmorrhagic mottling, irregular areas of coagulative necrosis. The blood (as in pancreatic hæmorrhage) may pass into the contiguous tissues, infiltrate the mesentery, and escape into the peritoneal cavity. Peritonitis may also be present. Fat-necrosis, appearing as opaque, yellowish-white specks and areas, 3 or 4 mm. in diameter, often surrounded by a zone of hæmorrhage, occurs in the fat of the mesentery, omentum, peri- and inter-pancreatic tissue, retroperitoneum, pericardium and other places. See **FAT-NECROSIS**, p. 526.

In the cases which macroscopically show hæmorrhages sufficient to obscure completely or to a large extent the parenchyma, microscopic examination demonstrates that the blood lies between or within the acini. The connective-tissue septa between the lobules are frequently much expanded and thickened, owing to the presence of the hæmorrhage, the blood-corpuscles not only lying in the tissue-spaces and pressing apart the connective-tissue fibrillæ, but also occupying similar spaces in the adipose tissue and appearing between the individual fat-cells. From these points the hæmorrhage extends into the acini, the amount being somewhat variable. In some instances it follows the fine connective-tissue septa between the acini, while in others it penetrates more diffusely into the substance of the gland, so that the red blood-corpuscles come to lie in intimate contact with the glandular epithelium, which may be displaced from the basement-membrane. The effects on the

arenchyma proper vary with the extent of the infiltration. Where the hæmorrhage is for the most part confined to the connective-tissue septa, the glandular tissue stains sharply and the cells appear quite normal, while, on the other hand, the intra-acinous hæmorrhage is commonly associated with vacuolation, increased granulation, and even necrosis of the cells. The disintegration of the gland may be most marked at some distance from the chief hæmorrhage, and the most extensive leucocytic infiltration, instead of being found where the hæmorrhage has been most profuse, may appear where the disturbance of the normal arrangement of the glandular epithelium is especially pronounced. In the early stages the connective tissue is quiescent, no multiplication of cells apparently taking place. The main blood-vessels remain open. The veins are much dilated, but are free from thrombi; they show, especially near the periphery of the vessel, an increase in the number of leucocytes, which is much less marked in the arteries. The majority of the smaller veins and arteries, as a rule, are open and show changes similar to those observed in the larger vessels—hyperæmia and leucocytosis. Occasionally thrombi (chiefly venous) occur in small vessels; the thrombi are largely fibrinous, but contain a few fragmented nuclei of white blood-cells. Very extensive hæmorrhages may occur in the gland and yet remain limited to the interlobular septa. Where this has happened, the gland-tissue presents a normal appearance, despite the manifest congestion of the blood-vessels in the septa. The products of the hæmorrhage may find their way into the branches of the excretory ducts, the epithelial lining of which appears perfectly normal.

Where coagulative necrosis has occurred, the glandular and connective-tissue cells are devoid of nuclei, granular, and in part disintegrated; the only cells of the foci in which the nuclei are preserved are emigrated leucocytes. The hæmorrhage is outside of these necrotic foci, and frequently outside of the mass of leucocytes, which forms as it were a collar immediately around the necrotic zones. In the most acute instances of this condition no changes of a progressive character are demonstrable in the connective-tissue. The condition of the blood-vessels varies. In the necrotic zones they are, of course, occluded; outside they may still be open and widely distended on account of the active hyperæmia. The zones of the necrotic tissue, even where red blood-corpuscles are absent, show much fibrin. The structure of the acini may still be demonstrable, the cells having an increased refraction, taking the acid stains, and being devoid of nuclei. This loss of nuclei is usually through lysis, but there are exceptions in which large numbers of nuclear fragments exist, particularly in the peripheries of the necrotic zones.

SYMPTOMS.—The onset is likely to be sudden and attended by violent colicky pains, referred chiefly to the upper part of the abdomen. Nausea and vomiting follow, and symptoms of collapse more or less severe, according to the severity of the attack. The abdomen becomes swollen and tense; the bowels are obstinately constipated. At first there may be no fever, but the temperature may rise later, the elevation being often preceded by a chill. Symptoms of collapse supervene, and death occurs usually between the second and the fourth day, or even earlier. Intestinal obstruction, or acute perforative peritonitis, is usually suspected; but cases

have been diagnosed *intra vitam* (Fitz, Thayer, Bloodgood), and even operated upon. With reference to the diagnosis, Fitz says: 'Acute pancreatitis is to be suspected when a previously healthy person, or a sufferer from occasional attacks of indigestion, is suddenly seized with a violent pain in the epigastrium, followed by vomiting and collapse, and in the course of twenty-four hours by a circumscribed epigastric swelling, tympanic or resistant, with slight elevation of temperature. Circumscribed tenderness in the course of the pancreas, and tender spots throughout the abdomen, are valuable diagnostic signs.'

(2) *Acute Suppurative Pancreatitis (pancreatic abscess).*—Two forms of suppurative pancreatitis have been met with: the abscesses may be multiple and small in size, when they are usually distributed throughout the gland; or they are larger, and single or, at most, few in number. Diffuse purulent infiltration is very rare. Multiple suppurative foci are usually due to metastasis; the larger abscesses are more frequently the result of the entrance of pyogenic micro-organisms along the pancreatic ducts.

ÆTIOLOGY.—The ætiology in the majority of cases is doubtful. Dieckhoff has pointed out three possibilities: (1) the infection may be hæmatogenous, pyogenic organisms, chiefly cocci, being brought to the pancreas in the circulating blood; (2) the micro-organisms may extend to the pancreas from a neighbouring viscus, as in ulcer of the stomach; (3) the pyogenic bacteria may enter the ducts from the intestine. Traumatism has been noted as an exciting cause. Of the reported cases, in twenty-four there was a single abscess, and in fourteen there were numerous small abscesses.

Primary abscess arises from infection of the ducts. As predisposing causes may be mentioned, pancreatic calculi, biliary calculi compressing the pancreatic duct, and tumours of the duodenum. Retention of the pancreatic secretion, and perhaps catarrhal inflammations of the duct, favour the entrance and multiplication of the pyogenic micro-organisms. Dieckhoff has traced the bacteria through the larger into the finest ducts, and thence into the acini; they also penetrate the walls of the ducts, and enter the peri-canalicular lymph-spaces and interstitial tissue. Chief among the bacterial forms which have been isolated are the pyogenic cocci, and bacilli of the group of *B. coli communis*.

Suppurative pancreatitis has been brought about experimentally. Doubtless the first to produce it was Claude Bernard, who injected quicksilver into the ducts. The injection of material containing bacteria (perityphlitic pus, Körte), and cultures of pyogenic organisms have usually sufficed to cause abscesses. Other irritants, such as turpentine, may also do so, although a chronic form of inflammation is the rule from the employment of this substance. The writer also obtained occasional suppuration from injections into the duct of acids and alkalis.

MORBID ANATOMY.—In consequence of the suppuration, necrosis of larger or smaller portions of the gland may occur. Indeed, the entire gland has been seen to have undergone necrosis and sequestration, the remains of the pancreas being found bathed in pus and occupying the cavity of the lesser omentum. Putrefactive changes may take place in the suppurating area when gangrene in the adjacent glandular tissue is likely to occur. From

the pancreas as a starting-point, the suppuration may extend to the peripancreatic tissues, or the cavity of the lesser omentum may become infected, so leading to an encapsulated abscess by closure of the foramen of Winslow. The suppuration may also extend to the retroperitoneal tissues and the pus pass towards the right kidney or the spleen, or follow the descending colon down to the pelvis. Through the use of artificial injections, Körte has proved the natural extension to be to the left side. The rupture of pancreatic abscesses may set up a generalised peritonitis. A not infrequent termination is by rupture into the stomach or intestine. Moore has reported an instance in which the abscess burst into the peritoneal cavity, and the pancreaticoduodenal artery. Venous thrombosis, involving the portal, splenic, and superior and inferior mesenteric veins, is not infrequent. Thrombosis of the femoral veins has been noted, and Körte has described parietal thrombosis of the splenic artery. Multiple metastatic abscess may follow the vascular thromboses originating from the pancreatic disease.

SYMPTOMS.—The symptoms of suppurative pancreatitis are not always well defined. The disease may begin suddenly, or may follow disturbances of digestion or biliary colic. Severe pain in the epigastrium and extending over the entire abdomen may be present. Cases without pain have also been described. Sensitiveness upon pressure in the epigastric region is almost constant. Nausea, vomiting, or retching are frequently present. The temperature usually shows an irregular elevation, but chills and delirium are less constant. Constipation is the rule, but in some cases diarrhoea has set in during the first twenty-four hours, or at a later period of the disease. Blood and foetid pus have been noted in the dejections after perforation of an abscess into the gut. The epigastrium is usually distended; in a few instances a tumour has definitely been made out in the upper abdomen. Jaundice is common, and fatty diarrhoea and glycosuria have been met with. After extension of the suppuration to the peripancreatic tissues and contiguous parts of the general peritoneum, the symptoms may belong entirely to these complications.

TREATMENT.—The history of the case, pain, and the presence of a tumour in the region of the pancreas, justify an exploratory incision. Körte advises exploratory puncture, especially when the suppuration has extended backwards towards the retroperitoneal tissues. The needle is introduced in the lumbar region; the withdrawal of cloudy fluid, mixed with fatty fragments, he regards as pathognomonic of pancreatic disease. It may happen that even during the operation the site of the abscess is made clear by the nature of the pus, its richness in fat, and the admixture of fragments of necrotic tissue. In rare instances the diagnosis cannot be made until a pancreatic fistula has developed. The condition, unless relieved by spontaneous rupture into the gut or by operation, is probably fatal. The course of the disease may cover a few days or several months.

(3) *Necrotic and Gangrenous Pancreatitis.*—Necrosis of the pancreas, varying in degree, is an accompaniment of the various forms of acute pancreatitis. It rarely occurs in the chronic types. Larger foci of destruction, the result of occlusion in the blood-vessels, may be the cause of inflammations. While the presence of microscopical and

macroscopical areas of necrosis are the rule in hemorrhagic pancreatitis, in the suppurative form sequestra are frequently contained within the abscesses. Their size is subject to great variation; the middle portion, the tail, or the entire gland may have become separated. Fat-necrosis has been urged as a cause of the glandular necrosis. This is believed to result from extension of the hemorrhage, which commonly attends the fat-necrosis, or from growth in size of the fat-necroses themselves. There is little basis for this view, the evidence at hand pointing rather to the production of fat-necrosis as a consequence of the pancreatic disease. That self-digestion of the pancreas may cause such necroses seems probable from the two instances of the condition reported by Chiari. Pathological conditions in contiguous parts may, by extension to the pancreas, set up necrosis.

There is no special morbid anatomy, histology, or symptomatology for this condition, seeing that it is closely related to hemorrhagic and suppurative pancreatitis. Its affinities with gangrenous pancreatitis are also very close.

Gangrenous pancreatitis may succeed the other forms of the disease described, and represents a stage in which, through the entrance into the already injured organ of putrefactive bacteria, complete tissue-death with subsequent decomposition ensues. The extent of the lesion depends greatly upon the primary exciting cause; there may be complete necrosis of the gland or parts or it, and this may follow either hemorrhage, acute inflammation, or purulent infiltration, while in exceptional instances it may occur after injury, or from extension of disease in neighbouring parts. Perforation of gall-stones, and consequent inflammation and putrefaction of the gland, as well as extension of gastric ulcerations to the pancreas, are established causes. In other cases the aetiology is obscure. Fitz thus describes the gangrenous gland: 'The appearance of the pancreas varied according to the duration of the disease. About the fourth day, the pancreas may be doubled in size, dark red and of somewhat diminished consistency. It may be red, on section, or mottled red and grey. The tip may be shreddy, or the entire gland may be transformed into a dark, slaty-coloured, stinking mass. The adjacent parts may be infiltrated with a discoloured purulent fluid, or the coils of the intestine near the pancreas may be united by recent adhesions together and to the under surface of the diaphragm. . . . On the tenth day the pancreas may be dark brown, dry, firm. It may have a hemorrhagic coating, or lie in a sponge-like mesh-work, infiltrated with dirty, green fluid. . . . Towards the end of the second week, the pancreas may be a soft, black, shreddy, sloughy, gangrenous mass, the central part being encapsulated by the peripheral portion. Between the pancreas and the transverse colon may be a large quantity of chocolate-like fluid, and large bluish-black clots. Or the tail and a part of the body may be soft, grey, discoloured, and infiltrated with a thin, ichorous fluid, while the parapancreatic tissue is partly purulent and partly ichorous. . . . A few days later, the pancreas may be a thin, flabby, friable, greyish band, lying in a cavity behind the stomach, and attached by a few shreds to the omental wall. . . . At the end of three weeks, the dark brown pancreas may lie nearly free in the omental cavity. . . . In the fifth week, the pancreas may lie free as if macerated, in a cavity ex-

tending behind the cæcum and descending colon, on both sides of the spine, as far as the pelvis. . . . At the end of seven weeks, the pancreas may be transformed into a cylindrical, shreddy mass of brownish-black, friable tissue. This may lie in the omental cavity, which is filled with offensive, black fluid, and communicates with the stomach and jejunum.' In two cases reported by Chiari, the necrotic pancreas was discharged *per rectum*, with recovery. In one case the sequestrum showed scarcely any indication of pancreatic structure; but instead there were larger and smaller islands of necrotic tissue, richly infiltrated with polymorphonuclear leucocytes, many of which were fragmented. Micro-organisms were present in immense numbers, among which diplococci, streptococci and large thick bacilli could be distinguished.

Gangrenous pancreatitis has rarely been produced in experiments upon the pancreas of animals, the procedures thus far employed in producing pancreatitis having yielded hemorrhagic and necrotic inflammations. When extensive injury has been inflicted upon the gland, death has resulted in a short time—12 hours to 3 days—presumably before putrefactive organisms have had time to enter the injured organ and increase. In two instances of diffuse hemorrhagic pancreatitis following the injection of artificial gastric juice into the duct of Wirsung, Pearce and the writer have noted invasion of the pancreas by gas-producing bacilli, and the production of extensive necrosis with dark discoloration. Sequestration, on account of the short duration of life, had not taken place.

The symptoms of gangrenous pancreatitis are those of suppurative pancreatitis. The diagnosis would be made upon the same general basis; confirmation would only be rendered possible by a surgical operation, the evacuation of the sequestered organ with the dejecta, or *post-mortem* examination. Peritoneal fat-necrosis is a very common attendant, and may be the 'sign-post' upon the opening of the abdominal cavity by the surgeon. See FAT-NECROSIS.

(4) *Chronic Pancreatitis* is characterised by a new growth of connective tissue with corresponding atrophy of the glandular structures. Two main forms are recognised: (1) a chronic inflammation extending from the ducts and met with in association with chronic catarrhal processes in the stomach and duodenum and in the bile-passages; (2) a chronic pancreatitis of hæmatogenous origin, resulting from toxic material in the blood, produced particularly by alcohol and in vascular disease (Dieckhoff).

An indurative pancreatitis which starts from the ducts (sialangitis pancreatica) is the common form. All conditions which favour the entrance of micro-organisms into the duct (cholelithiasis, carcinoma) predispose to it. Occlusion of the ducts by pancreatic calculi also produces chronic pancreatitis. The new tissue grows about the blood-vessels, around the pancreatic ducts and the nerves, and eventually increases the interstitial bands running between the lobules and separating the acini. The secreting structures undergo fatty degeneration and atrophy, finally disappearing entirely. In closure of the pancreatic duct by stone or chronic inflammation, the pressure of the retained secretion causes atrophy and disappearance of the glandular cells, with a subsequent new growth of connective tissue. The interlobular adipose tissue tends also to become

increased. The sclerosis may involve the whole organ, converting it into a fibrous strand, in which few or no remains of glandular tissue may be found; or it may affect a circumscribed portion (especially the head) of the gland. Riedel has emphasised the occurrence of chronic inflammation of the head of the pancreas in association with gall-stones, and has seen the condition relieved after their removal. Körte has described compression of the common bile-duct by a small nodule of the pancreas involved in chronic pancreatitis. Experimental sclerosis can be produced by a ligaturing of the ducts in animals, and by injections of blood and irritants into the duct of Wirsung (Körte and Flexner).

Indurative pancreatitis may result from endarteritis obliterans, and is then to be regarded as a part of a general process affecting the organs of the body. The degree of connective-tissue growth is variable, and may be only small in amount; or the gland may be reduced to a 'mass of fatty tissue.' The coeliac axis shows advanced arterio-sclerosis with calcification. Syphilis is an undoubted cause of indurative pancreatitis. Its ætiological significance is seen at once in congenital syphilis. Rokitsky and Birch-Hirschfeld dwelt on the syphilitic sclerosis of the pancreas, and pointed out that it occurs both with and without the presence of gummata. In the severer grade of the congenital disease the interstitial portion is increased to such an extent that the secreting tissue may be entirely destroyed. Alcoholism is another cause of connective-tissue proliferation. Sclerosis of the pancreas may be associated with hepatic cirrhosis. A similar association with chronic nephritis has been noted. Hansemann has drawn certain analogies between the small granular kidney and the so-called simple atrophy of the pancreas.

The chief interest in sclerosis and atrophy of the pancreas relate to their association with diabetes mellitus, which will be discussed later in the present article.

5. **Pancreatic Cysts.**—*Retention-Cysts* are the most common (p. 360). The obstruction may be in the main ducts or in the smaller branches. It may result from compression or obliteration of the ducts, or both combined. The most frequent cause is chronic indurative pancreatitis, in which the new growth of connective tissue compresses and obliterates the ducts. A similar condition has, in a few instances, been produced experimentally; once by Miroloix, who injected a mixture of soot and vaseline into the duct of Wirsung, after tying the accessory duct, and again by the writer, who observed cysts develop in the pancreas of the dog, after the injection of dilute acids (hydrochloric, sulphuric). When the animals were killed after periods of from three to four weeks, the pancreas was found contracted and indurated. The cysts contained an opaque glutinous fluid. Tumours pressing upon the main duct may give rise to cystic dilatation. Peripancreatic fibrous induration, enlarged lymphatic glands, and gall-stones within the common duct may be the sources of pressure. Pancreatic calculi are among the important causes. The concretions may be in the main ducts as well as in the smaller ones, and the cystic dilatations may be single and large—as large as a child's head—or smaller and multiple (*varanula pancreatica*). It is uncertain whether catarrhal inflammation can cause closure of the pancreatic duct: cysts from this source are unknown; nor have cysts been described

as a result of the compression of the duct by tumours of the pancreas itself. An unusual cause is the entrance of an *Ascaris lumbricoides* into the duct of Wirsung. That necrosis of the pancreas may lead to the production of cysts is shown by a case reported by Tricomi, in which, besides the presence of concretions, there was necrosis of the gland; moreover, in the writer's experiments the remains of pancreatic tissue were found among the contents of the cysts. Traumatism has been given as a cause of cysts. Blows on the abdomen, or constantly repeated pressure, are the most common forms of injury. In this connection, Osler mentions severe massage. The contents of the cysts are usually bloody, though they may be clear or yellowish. Hemorrhage may have taken place into the retention-cysts, either shortly before operation, or at some more remote period. From the character of the wall and its relation to the ducts it is possible to decide whether the cyst has been preformed or not. Cases of true apoplectic cysts, however, have been reported. When they arise independently of retention-cysts, they must be regarded as curiosities.

Proliferation-Cysts.—In proliferative cysts there is no indication of any relation to retention or simple inflammation (p. 361). They are correctly regarded as representing a neoplastic change, being analogous to the proliferation-cysts of the kidney and ovary. They are usually multiple, and vary in size from a pea to a hen's egg. From the fibrous coats of their walls, outgrowths in the form of excrescences are developed; these, as well as the inner surfaces of the walls, are covered with epithelium. The wall itself also contains acini, which often present lumina. In Menetrier's case there were cysts in the liver also. Echinococcus-cysts of the pancreas appear to be very rare. Cysts are seated more often in the tail than in the head of the pancreas. The quantity of fluid contained within the cysts varies greatly. The average is from one to three litres, and the maximum 20 litres. In rare instances the contents are colourless, pale yellow, or yellowish-green. Usually they are brown in colour, sometimes coffee-coloured, or reddish-brown. Not infrequently they are turbid, muciginous, and more rarely gelatinous (colloid) or purulent. The admixture of blood, whether recent or old, causes profound changes. The fluid may be dark red and contain coagula, or present a chocolate-brown colour. The reaction of the fluid is usually alkaline, sometimes neutral, while in one instance it was acid. The specific gravity varies from 1·007 to 1·028. The amount of albumen fluctuates between 0·56 per cent. and 10 per cent. It is composed chiefly of serum-albumen and globulin. Metacasein and peptone have been found in isolated cases. Sugar has only rarely been found; cholesterol is common; urea, leucine, and tyrosine are unusual, while the pancreatic ferments have not always been demonstrable. In some cases one, in others all the ferments have been discovered.

SYMPTOMS.—The development of pancreatic cysts often proceeds so insidiously, that until they reach a large size no subjective symptoms manifest themselves. Disturbances of digestion, preceding the appearance of a tumour, and extending over a long period, as well as painful colicky attacks, nausea and vomiting, together with progressive enlargement of the abdomen, have commonly been noted. Pancreatic salivation is rare. Emaciation is noted by Osler as a very common symptom. Some of the main symptoms may be referable to

chronic pancreatitis, which is the most frequent cause of the condition, or to disturbances in adjacent organs upon which the cyst exerts pressure. The jaundice may be marked and enduring. Adhesions between the cysts and neighbouring organs may arise, and if the latter chance to be hollow viscera, rupture into them may take place. Hæmatemesis has resulted from rupture of a blood-containing cyst into the stomach, and a very watery stool, with disappearance of the abdominal tumour, has been noted when the cyst has broken through into the intestine.

The swelling caused by the cyst may be regional or produce a general enlargement of the abdomen. Usually it is limited to the epigastrium, and inasmuch as the tail and body are more frequently affected, it is most likely to be marked in the left epigastrium, the mesogastrium, and the left hypochondriac region. Under certain circumstances the abdomen may reach an enormous size. The tumour is smooth; fluctuation is commonly present, but may be absent if the cyst is well filled. On percussion, the note is completely or partially tympanic, depending upon the condition of the overlying hollow viscera. The movements of the diaphragm may cause oscillations of the tumour, and lateral movements may be obtained through the abdominal walls.

TREATMENT.—Cysts of the pancreas come into the category of surgical diseases. Puncture, total removal, partial extirpation with drainage, and incision and drainage have all been practised. In seven cases in which puncture was done, five deaths occurred; in 11 cases of total extirpation, two deaths; in 12 cases of partial extirpation, four deaths; in 12 cases in which incision was done in two operations, there was one death (due to diabetes); and in 58 cases with immediate incision, there were seven deaths (Osler).

6. The relation of diabetes mellitus to disease of the Pancreas.—Extirpation of the pancreas in the dog causes, without exception, diabetes of severe degree. The elimination of sugar by the urine reaches 10 per cent. or more; the animals, notwithstanding their ravenous appetites, lose weight and flesh; they exhibit pronounced thirst, and ultimately become very weak and succumb. Complete extirpation of the gland in cats, rabbits, swine, toads, and frogs, is followed by similar results. In birds, removal of the pancreas gives rise to diabetes, but without causing a constant glycosuria. The blood, on the other hand, shows considerable increase in its sugar-content (hyperglycæmia). Dogs, after extirpation has been practised, may begin to secrete sugar from the kidneys as early as six hours after the operation. The amount gradually increases until on the third day it reaches 8–10 per cent. The maximum recorded is 22 per cent. The highest percentages are maintained until toward the end, but finally, and when the emaciation has become very great, the quantity is diminished. As the sugar falls to the minimum, acetic acid, acetone, and oxybutyric acid appear in the urine. The acme of the secretion of sugar is reached from carbohydrate food; but a pure albuminous diet does not reduce the amount below 5·6 per cent., while fasting for a period of seven days does not suffice to cause its entire disappearance (von Mering and Minkowski). Incomplete removal of the pancreas is not necessarily followed by diabetes. If one-fifth of the gland be left either *in situ* or transplanted beneath the skin, the diabetes may be averted.

Should the amount left behind sink to $\frac{1}{4}$ or $\frac{1}{17}$, or should a larger remnant suffer later in its nutrition and undergo atrophic change, a mild form of diabetes arises which, however, tends, through progressive degenerative changes in the gland, to become more severe, and to terminate fatally. The voided sugar is glucose. Saccharose, maltose, lactose, levulose, and galactose are eliminated chiefly as dextrose. Traces of levulose and galactose appear, however, in the urine. Hyperglycemia goes hand in hand with glycosuria. The former is demonstrable four hours after ablation, and reaches its height in 24 hours (Lépine). Towards the end of the disease, when the glycosuria diminishes, the hyperglycemia also falls.

Diabetes, the result of total extirpation of the pancreas, is fatal. No other organ can act vicariously in regulating the carbohydrate metabolism of the body. Hence the function of the pancreas, the disturbance of which produces diabetes, may be regarded, in Minkowski's sense, as specific. This is not, however, equivalent to saying that the pancreas is the only organ, the disturbance of whose functions is capable of producing diabetes. It is probable that other organs also preside over the carbohydrate metabolism, although perhaps in a less degree, and that the pancreas may act vicariously for them, although they themselves have not the power to be substituted for the pancreas (Naunyn). Reale and Minkowski have shown that the removal of all of the salivary glands in the dog is followed by a transient glycosuria reaching 3 per cent. of sugar.

There are no records of complete removal of the pancreas in human beings. Partial resections of the gland have been followed by glycosuria or diabetes. In the latter cases, the interval between the operation and the appearance of the symptoms was as great as a year and nine months, and the result may have depended upon a progressive degeneration. That the pancreas in human beings shows marked pathological changes in cases of diabetes is shown by numerous observations. Of the causes of the pathological changes in the pancreas which produce diabetes, the chief one is supplied by concretions in the ducts. Of 72 cases 14 were due to pancreatic calculi (Hansemann). The pancreatic changes consist of secondary atrophy (see CHRONIC PANCREATITIS, p. 1153). Next in frequency come the primary atrophies, fibrous indurations, and instances of interstitial lipomatosis. Attention should be paid to another possible explanation of pancreatic atrophy, namely, a cachectic condition which may be the result and not the cause of diabetes (Friedreich, Naunyn). Hansemann has undertaken to distinguish between the two forms of pancreatic atrophy. In the cachectic form, the organ is cylindrical, and sharply demarcated from its surroundings. Microscopically, the stroma and glandular cells are uniformly atrophic. In diabetical atrophy, there is interstitial pancreatitis; on account of adhesions, the gland is with difficulty separated from its surroundings, and presents a brownish coloration (although it is not pigmented), is of smoother texture, and microscopically shows hypertrophy of the stroma and atrophy of the secreting cells and islets of Langerhans (*intra-acinous pancreatitis*). Other forms of interstitial pancreatitis may be associated with diabetes. Hansemann has seen diabetes in an early case of interstitial pancreatitis, and is of the

belief that a particular form of pancreatitis, which he calls granular atrophy, is always associated with diabetes. Hanot has described cases of bronzed diabetes (*diabète bronzé*) in which, besides pancreatic disease, hypertrophic cirrhosis of the liver has been present (p. 889). Opie says, 'clinically, the picture is one of a rapidly fatal diabetes mellitus associated with cirrhosis of the liver, usually the hypertrophic variety. Bronzing of the skin is not constant, but has been present in the majority of cases. At autopsy, has been found a deep pigmentation of the liver and pancreas, associated with cirrhosis and interstitial pancreatitis.' Opie has recently described an instance of pancreatitis in which the lesions of the pancreas were limited to the islets of Langerhans, which showed hyaline degeneration.

Although the evidence is not complete and unmistakable, yet it must be regarded as proving that the pancreas in man, as in animals, is intimately concerned in regulating the carbohydrate metabolism of the organism, and that a failure of the function of the organ in man—analogueous to total extirpation in animals—is followed by symptoms of diabetes. That this failure is independent of the digestive function is proven by the results of ligature and occlusion of the ducts, and that it depends upon an internal secretion supplied by the pancreas to the blood is highly probable. Whether this hypothetical secretion is the product of the cells of the islets of Langerhans is unproven. Should future study prove this view to be true (and the possibility is strengthened by Opie's observation) a closer differentiation of pancreatic disease than exists at present will be rendered necessary, and in this light the discrepancies in the relation of diabetes and pancreatic diseases, now impossible of explanation, may receive their solution.

The search for the cause of pancreatic diabetes has given rise to much ingenious speculation and numerous experiments. Thus far no satisfactory theory has been advanced, nor have the views put forward found support in experiment. Von Mering and Minkowski proposed two alternatives: (1) there takes place after extirpation of the pancreas an abnormal accumulation of injurious substances which it is the function of the gland to destroy; or (2) an important and irremediable function in the regulation of the carbohydrate metabolism is abolished by the removal of the pancreas. The former alternative was abandoned by Minkowski himself in later writings. The latter still has the greatest number of adherents, although it possesses a purely hypothetical basis; its adoption would bring the pancreas into line with other organs, e.g. thyroid gland and adrenals, which secrete internally or exhibit, according to Hansemann, a positive function. The manner of the regulating mechanism of the internal secretion is differently conceived of by different writers. Lépine has concluded, upon an experimental basis, that the normal pancreas contains a glycolytic ferment, which finds its way into the lymph and blood, where it is contained within the white blood-corpuscles. The ferment controls the consumption of sugar by the tissues. Its absence is followed by hyperglycemia and diabetes. The existence of the hypothetical ferment has not been rendered more probable by the results of subsequent experiments, carried out by a number of investigators, and the occurrence of a specific glycolytic power in the blood has, indeed,

been rendered highly doubtful. Chauveau and Kaufmann have proposed the opposite hypothesis. In opposition to the view that diabetes results from diminished sugar-destruction, they have set up the theory that it depends upon increased sugar-production by the liver. In respect to this function, they regard the liver and pancreas as closely related and mutually dependent organs. The pancreas regulates, through the nervous system, the production of sugar by the liver. The inhibitory centre is located in the medulla oblongata, and the centre of irritation is in the upper cervical region of the spinal cord. The pancreas acts upon the centres in opposite ways. The 'nervous' theory, however, was not wholly confirmed by further experiments; and Kaufmann in a later paper admits a partial direct influence of the pancreas upon the functions of the liver. Minkowski is certain that in experimental pancreatic diabetes, the fault is not increased production of sugar, but disturbances of consumption. The brothers Cavazzani would explain diabetes following extirpation of the pancreas as brought about by consequent alterations of the liver. Experiments have shown that irritation of the coeliac plexus causes an increase of sugar in the hepatic blood. A similar irritation may follow removal of the pancreas. Hence an excess of sugar is produced in the liver, the metabolism of that organ is increased, and degenerations result. The theory is scarcely tenable in view of the effects of the transplantation of the pancreas. Thus far, none of the theories advanced suffices to explain all of the phenomena observed. What appears to be beyond doubt is that diabetes results from the failure of a special internal function of the pancreas, and that it is not due to nervous lesions or to the absence of the digestive secretion of the pancreas.

7. Tumours.—*Carcinoma*.—The most important neoplasm of the pancreas is carcinoma, which, while by no means frequent, is probably less rare than statistics would seem to indicate. Primary carcinoma of the pancreas is, however, much less common than the secondary disease. Decision as to the primary seat of the cancer is not always easy, since tumours of similar structure may spring from the duodenum. Even the microscopical examination will not always suffice for making a distinction, and carcinomata springing from the ducts may grow to simulate cylindrical-celled epitheliomata.

The most common seat of the tumours is the head of the organ. The most common form is the scirrhus cancer; only rarely are encephaloid and colloid or cylindrical-celled tumours found. When it is the seat of carcinoma, the pancreas is enlarged and the tumour-nodules vary in size from that of a bird's egg to that of a child's fist; only rarely have larger masses been observed. The portion of the organ not implicated by the tumour may be entirely normal, or show only an increase of connective tissue. By extension of the tumour, the liver, stomach, duodenum, and gall-bladder may become implicated. The omentum, mesentery, large intestine, and other organs suffer less frequently. On account of the predilection for the head of the pancreas, the tumour frequently, even at an early period, compresses the common bile-duct. Compression of the duodenum and stenosis of the pylorus may also result. More rarely compression of the colon, the portal vein, the aorta, the splenic and mesenteric vessels, and inferior vena cava has been noted.

Males are affected nearly twice as frequently as females. The disease has been observed in early life, but its chief incidence has been noted in the four decades, from the thirtieth to the seventieth year inclusive.

SYMPTOMS.—A satisfactory diagnosis is not often possible. The symptoms arise more especially from implication of adjacent organs, and only rarely can be traced to the pancreas itself. Disturbances of digestion appear early; there is more or less loss of appetite, or, on the other hand, abnormal sensations of hunger, pressure, and discomfort following meals, fullness in the epigastrium, heart-burn, eructations, nausea, and even vomiting. As the disease progresses these symptoms become even more marked. Complete anorexia, a positive loathing of food, especially meat, may supervene. Whether or not these symptoms are referable wholly or in part only to implication of the stomach and duodenum has not been decided. There are, however, cases in which the appetite and functional activities of the stomach do not suffer, although, despite the ingestion of a considerable amount of food, there is progressive loss of weight and strength. The disturbances of indigestion are increased if the tumour compresses the pylorus and duodenum, since, as a consequence, dilatation of the stomach and stagnation of the ingesta occur. Perforation of the tumour into the stomach or duodenum is associated with hæmatemesis. Chemical examination of the gastric contents has shown, in a few instances, absence of free hydrochloric acid, although the stomach was not anatomically affected. On the other hand, a case is recorded in which, although the pylorus was compressed, the gastric contents showed 2.6 per cent. of hydrochloric acid.

One of the most notable symptoms is jaundice, which occurs, often early in the disease, not so much in consequence of invasion of the parapancreatic structures as from compression of the common bile-duct in its course through the head of the pancreas. While its onset may be sudden and follow an attack of colic, it usually appears gradually, and shows a steady increase in intensity. On the other hand, jaundice may be entirely wanting.

As indicating interruption of the normal functions of the pancreas, fatty stools are to be noted. The condition has been not infrequently observed. Chemical examination has revealed one-fourth of the entire content of the dejecta to consist of fat. There is disturbance also of the proteid-digestion; the fæces contain undigested muscle, &c., and the total volume of the stools is greatly increased. Instances have been observed in which much of the food passed through the intestine undigested. The exclusion of bile also produces characteristic changes in the stools.

Pain in the epigastrium is usually present; it may be intense and continuous or intermittent. After the extension of the tumour to other viscera, the pain may cease to be localised. Sensitiveness to pressure over the region of the pancreas may become a marked and distressing symptom. After a time, a tumour may be palpated, although the fact that the pancreas lies behind the stomach, and is covered in part by the left lobe of the liver, makes this sign less reliable. Osler estimates that a tumour or resistance is to be made out in 20 to 25

per cent. of all cases. The tumour may be smooth, nodular, or lobulated; it may be sharply circumscribed, and when limited to the head of the pancreas will be found to the right of the vertebral column and in the region of the pylorus. Except in rare cases, it is fixed and immovable. Pulsation, conducted from the aorta, may be observed, and has led to a wrong diagnosis of aneurysm. Confusion with the distended gall-bladder has also occurred, and is a real danger. In some cases two tumours have been made out, one of which was an enlarged and turgid gall-bladder. Pressure of the tumour upon the portal vein has produced ascites: the exudate is clear and serous, and only rarely has chylous fluid been observed (Senti). The enlargement of the spleen and appearance of hæmorrhoids doubtless depend upon compression of the vena porta. Pressure upon the ureter has produced hydronephrosis (Récamier).

General failure of nutrition, increasing epigastric pain and cachexia are present towards the end. In pancreatic carcinoma, however, the cachexia develops relatively early, so that some authors have viewed it as especially characteristic of this form of the disease. The volume of the urine may be increased; albumen is commonly found, sugar much more rarely. Marallié found among fifty reported cases the occurrence of sugar in thirteen, and he expresses the opinion that if looked for earlier it might possibly be found more frequently. Cases have been reported in which it was found at certain stages, but disappeared just before death. On the other hand, cases of complete destruction of the gland by cancer have been noted without the presence of sugar in the urine, a fact attributed by Hansemann to the persistence of the power of internal secretion in the cancer-cells.

The points of greatest diagnostic importance are: intense and permanent jaundice, dilatation of the gall-bladder, rapid emaciation, and the presence of a tumour in the epigastric region. Of less importance are features pointing to the disturbance of the functions of the gland (Osler).

The duration of the disease varies greatly. Some cases end fatally two to three months after the appearance of the first symptoms. Other cases have lasted as long as two years. Most authors take six months as the average duration. The prognosis is always grave. Several patients (six according to Körte) have recovered after surgical operation. Drugs are useless, although certain concomitant symptoms call for the exhibition of appropriate medicaments.

Sarcoma of the pancreas is a rare disease. Of those described, the majority have been secondary. On this account the type of the tumour has varied with that of the original growth.

8. **Tuberculosis.**—Miliary tubercles as a part of the disseminated disease are not uncommonly met with. Larger tuberculous foci occur much more rarely. The chief mode of propagation is hæmatogenous; but infection through the duct would seem to be possible, although no positive instances are on record. Tuberculous lymphatic glands may become united to the pancreas by adhesions, and growth take place into the pancreas. No symptomatology of tuberculosis of the pancreas is known, and no treatment is applicable. The disease has been revealed accidentally by the surgeon, and Sandler has removed a portion of the gland on account of tuberculosis with successful results.

9. **Syphilis** occurs under two forms: a chronic indurative pancreatitis and gummata. Occasionally both are found combined. The chronic indurative form is met with chiefly as an accompaniment of congenital syphilis, less often as a result of the acquired disease (see CHRONIC PANCREATITIS, p. 1153). The gummata in congenital syphilis may be numerous and miliary in size; in the acquired disease they reach a larger size, but are few in number or occur as solitary tumours. In Schlegenhauer's case the gumma was as large as a hazel-nut. The condition has no especial symptomatology; so far as known the clinical manifestations are those of a chronic interstitial pancreatitis. See also PANCREATIC CONCRETIONS, p. 334.

SIMON FLEXNER.

PANDEMIC DISEASES (πᾶν, all; and δῆμος, the people).—Epidemic diseases which affect groups of several countries or the world generally. See EPIDEMIC; and PERIODICITY IN DISEASE.

PANTICOSTA, in the Spanish Pyrenees.—Thermal waters. See MINERAL WATERS.

PAPILLOMA (*papilla*, a nipple, a wart).—A tumour composed of hypertrophied papillæ, either of the skin, or of a mucous or a serous membrane. See TUMOURS.

PAPULE.—SYNON.: Pimple; Fr. *Papule*; Ger. *Papel*.—A small, solid, circumscribed prominence of the skin. A papule may be conical, hemispherical, or flat at the top. The lesion may be the result of inflammatory exudation, of new-growth, or of accumulation of some secretion deep in the skin. See LICHEN PLANUS (p. 871); and DYSIDROSIS.

PARACENTESIS (παρά, at the side; and κεντέω, I prick).—SYNON.: Tapping; Fr. *Paracentèse*; Ger. *Paracentese*.—The term Paracentesis is rapidly becoming obsolete, and replaced by other words such as aspiration, exploration, or drainage. The term, however, is still applied to 'tapping' operations on the abdomen, thorax, and head.

The insertion of a hollow tube, whether in the form of a cannula or of the modern exploring needle, is practised for two distinct objects: (1) For the purpose of diagnosis, i.e. merely to ascertain the presence and nature of fluid in a suspected region; (2) For the purpose of treatment, i.e. with the object of removing the fluid from the cavity. For diagnostic purposes an exploring needle is still constantly employed when fluid is suspected in the pleural cavity, lungs, or pericardium. On the other hand, the employment of this method in the case of the abdomen cannot be too strongly condemned. In this way vascular tumours have been punctured, and the patients have died from the resulting hæmorrhage. Collections of pus or of decomposing urine, as in certain cases of hydronephrosis, have been pierced by the needle, and the fluid has leaked into the peritoneal cavity and caused fatal peritonitis. The writer has seen a patient bleed to death owing to a few punctures that were made into a leucocythæmic liver with a view to localising a suspected hepatic abscess. See ASPIRATOR.

1. **Paracentesis Thoracis.**—The methods employed for diagnostic purposes and for treatment in surgical diseases of the pleuræ, lungs, and

pericardium will be dealt with in the articles PERICARDIUM, Surgery of; and PLEURA, Surgery of.

2. **Paracentesis Abdominis.**—Practically the only condition for which paracentesis is performed is ascites. The best instrument for this operation is Thompson's syphon-trochar, or one of its many modifications. In this instrument the cannula is fixed to the handle and has a lateral opening about its middle to which a long indiarubber tube is attached. The trochar is continued through the handle of the instrument and terminates in a button. The instrument is inserted in the ordinary way, the trochar is then drawn back until its head is past the lateral opening in the cannula, through which the fluid will then flow. The indiarubber tube must be carried into a vessel containing carbolic-acid solution. The result is that a syphon action is established of sufficient force to exhaust the cavity; at the same time the accidental entrance of air is rendered impossible.

In the case of the abdomen it is better not to use any apparatus that exerts any marked degree of suction. The operation is performed in the following way: The abdominal wall should be thoroughly cleansed with soap and water and then with turpentine. The bladder and rectum should be empty, and the maximum area of dullness definitely ascertained by percussion. The distended abdomen is then surrounded by a sterilised many-tailed bandage, and a small opening with a pair of scissors may be made in this just before the instrument is inserted. In ordinary cases it is best to puncture in the middle line, but if there be an enlarged uterus or some abdominal tumour it may be more convenient to perforate in the linea semilunaris or some other spot. If possible, the patient should be placed in a chair which can be tilted backwards if necessary in the event of the patient fainting. If the instrument is sharp a local anæsthetic is not necessary. It is sometimes advisable, in order to allay the apprehensions of the patient, to inject a little sterilised water or β -eucaine. The instrument is pushed firmly and quickly through the abdominal wall, and the trochar is then withdrawn leaving the cannula in place. As the fluid gradually escapes the bandage can be tightened by the nurse or assistant. If the patient shows any signs of collapse it is advisable to remove the cannula, or, at any rate, to stop the flow of fluid, and place the patient in a horizontal position until he recovers sufficiently for the evacuation to be continued. On withdrawing the cannula the wound in the skin may gape a little, in which event one or two stitches should be inserted. The dribbling away of fluid through the puncture-hole is, if anything, beneficial, and an antiseptic dressing removes all fear of septic invasion. *See also* PERITONEUM, Acute Inflammation of; and PERITONEUM, Tuberculosis of.

Paracentesis Capitis.—This operation is sometimes performed in cases of chronic hydrocephalus. When the intra-cranial pressure is very high there is improvement as soon as sufficient fluid has been let out. Within a short time, however, the former tension is generally again reached. Of recent years intermittent withdrawal of fluid by means of a trochar has been tried on a large scale, but with few, if any, instances of permanent benefit. If it is advisable to withdraw some fluid in any given case a small-sized trochar of ordinary shape is sufficient. No aspiration of any kind should be employed. The skin having been properly cleaned

the trochar is inserted through the anterior fontanelle, at some little distance from the middle line, so as to avoid wounding the superior longitudinal sinus; the cerebro-spinal fluid immediately spurts out with considerable force. Very soon, however, the fluid ceases to flow, excepting a few drops with each expiratory movement. The cannula is then withdrawn and the puncture closed with collodion.

HENRY PERCY DEAN.

PARAD, in Hungary.—Sulphate-of-iron waters. *See* MINERAL WATERS.

PARÆSTHESIA (*παρά*, beside, hence amiss, incorrectly; and *αἴσθησις*, sensation).—A term applied to abnormal sensations experienced by a patient, distinct from mere excess or diminution of feeling; for example, tingling, itching, and formication. *See* SENSATION, Disorders of.

PARALDEHYDE-HABIT.—*See* HABITS.

PARALYSIS (*παράλυσις*, weakness, palsy).—By paralysis is meant the inability to move voluntarily a certain muscle or muscles, or to appreciate any of the ordinary sensory stimuli. This implies an interruption or impairment of the continuity which normally exists between the peripheral apparatus and the central nervous mechanism. Strictly speaking such an interruption may either be in the centripetal or sensory structures, leading to impaired or disordered sensibility, or in the centrifugal or motor structures, causing impairment or loss of motor power, or may involve both simultaneously. Sensory impairment, however, may, on account of the erroneous impressions which reach the centre and determine or guide movement, lead to what appears to be motor paralysis. Locomotion, and the accurate use of the upper limbs, may thus be rendered impossible. Such a condition is seen in the ordinary form of locomotor ataxy or tabes dorsalis, and in cerebellar disease. In some cases we have to deal with disorder or impairment of both sensory and motor mechanism, but in the great majority of cases of paralysis the essential lesion is one of the motor apparatus, and to this we shall direct our chief attention.

The motor apparatus consists of nervous and muscular elements. It is true that diseases of bones and joints also lead to interference with motor power, and to that extent may be regarded as causes of paralysis. But such conditions do not necessarily imply any lesion of the nervous or muscular apparatus, and need not be considered here. So that in reference to the causes of paralysis we have to consider only diseased conditions of (1) the nervous system; (2) the muscular apparatus.

The motor nervous system consists of two elements or neurons—the upper motor segment, or upper neuron, comprising the pyramidal cortical cells, and the fibres of the direct and crossed pyramidal tracts, situated respectively in the anterior columns, and the lateral columns of the spinal cord. The lower motor segment or lower neuron comprises the cells of the anterior horns, the motor nerve-fibre, and its termination in the muscle. Between these two neurons it is thought that there is no absolute continuity, but that there is such close contiguity between the branching terminations of the pyramidal fibre and the pro-

cesses of the cells of the anterior horns that the transmission of impulses is rendered quite easy.

Such is the motor nervous mechanism for the limbs, and the parts of the body generally related to the spinal cord. Certain muscles, however, are not supplied from the spinal cord, but from the cranial nerve-nuclei. For these, of course, there is no fibre in the pyramidal tract of the cord, although there is the analogue to this in the fibre which connects the cortical cell with the cell in the nucleus of the cranial nerve related to it, this cell being itself the homologue of that in the anterior horns of the spinal cord, and the fibre from it to the muscle being an ordinary motor nerve-fibre. Thus a muscle in the face is supplied by a fibre from the facial nucleus in the pons, the cells of this nucleus being closely analogous to those of the anterior horns in the spinal cord, and in, at least, close contiguity to the terminations of the fibres which are a direct continuation of the pyramidal cells in that part of the cortex known as the face-area. So that in the parts related to the cranial motor nerves also, we have an upper and lower motor segment or neuron—the upper comprising the cortical cell and its continuation to the vicinity of the nuclear cell, and the lower comprising the nuclear cell and its nerve-fibre to the muscle.

The symptoms accompanying lesions of the two neurons are as a rule quite distinctive. If the lesion is one of the *upper neuron* there is present, loss of power in proportion to the severity of the lesion, and distributed according to its situation. Rigidity or spasticity is also as a rule present, and accompanying this exaggeration of the deep reflexes. If the lesion is such as to affect parts which subserve the lower limbs ankle-clonus is frequently present, its presence or absence depending upon the severity of the lesion. The plantar reflex is also modified, so that the toes, instead of being, as they normally are, flexed, on tickling the sole, are extended (*see BABINSKI'S SIGN*). Along with these symptoms of loss of power, rigidity, and increased deep reflex the *nutrition* of the parts concerned is unimpaired, and the *electrical reactions* are not in any way altered. A common example of such a condition is hemiplegia, the result of a lesion in the cortex or just under it, or, as often happens, in the internal capsule. In such a case the lesion is one of the upper neuron, and the symptoms are those just described—loss of power, spastic rigidity, exaggeration of deep reflexes, and intact nutrition. It is true that in some cases of hemiplegia there is impaired nutrition of the affected limb or limbs, but this is almost, if not quite, invariably associated with some arthritic changes, and really independent of the lesion of the neuron. Sensory impairment may also be present, the result of involvement in the lesion of sensory fibres. Another example is furnished by the ordinary case of so-called lateral sclerosis or spastic paralysis. In this condition the disease is one of the pyramidal tracts in the cord—part of the upper neuron—and in this condition also there is loss of power, spastic rigidity, exaggeration of deep reflexes and unaltered nutrition, and the muscles respond normally to all electrical tests. It must not be forgotten that in many cases of, e.g., spinal caries or other condition giving rise to inflammation of the spinal cord (myelitis) there is, in addition to the ordinary symptoms of disease of the upper neuron, some impaired sensibility, perhaps also some muscular wasting and trophic changes. But

these additional symptoms are the result of disease affecting other structures which are situated close to that part of the upper neuron involved in the diseased condition.

If the *lower motor neuron* is affected there is an entirely different set of symptoms. Besides the loss of power there are wasting, impairment of nutrition, coldness and blueness of extremities or other evidence of trophic disturbance, impairment or loss of deep reflexes, and altered electrical reactions. The alterations in electrical reactions may briefly be described as reduced or suspended reaction to a faradic current and an altered galvanic reaction—altered, perhaps, not only in the quantity of the reaction, but also in its quality (*see ELECTRICITY IN MEDICINE*). Examples of such an affection are found in such a disease as the ordinary infantile spinal paralysis, in which the lesion is one of the cells in the anterior cornua of the spinal cord; in the ordinary form of Bell's paralysis—facial paralysis—in which the lesion is one of the facial nerve as it passes through the temporal bone; in multiple alcoholic neuritis, in which the peripheral nerves of the limbs are the parts principally and often exclusively affected, and in post-diphtheritic paralysis. In all these forms of paralysis we have loss of power, muscular wasting, impaired or lost deep reflexes in the parts affected, trophic changes, and altered electrical reactions; so that it is impossible to mistake them for diseases of the upper segment. It is true that in multiple neuritis there is often a kind of rigidity present, but it is not of the spastic type found in lesions of the upper neuron, but is dependent upon structural alterations and contraction of the muscles themselves, the result of interference with their nutrition.

One disease of the motor nervous system merits particular attention here because it is one in which both the upper and lower neuron are affected—the disease known as amyotrophic lateral sclerosis. As its name implies, this is a disease in which symptoms of lateral sclerosis are associated with those of muscular atrophy; so that the prominent symptoms are loss of power, spastic weakness and muscular wasting. In some cases the spastic weakness is the first sign—affection of the upper motor neuron; in other cases the muscular atrophy is the first sign—affection of the lower motor neuron; in other cases there is evidence that the spastic condition and the muscular atrophy are simultaneous in onset. It seems likely that in this disease we have to deal with a degeneration of the whole motor system, and that this degeneration may show itself in some cases first in the upper neuron, in other cases in the lower, while in still a third class the evidence may point to a simultaneous affection of both neurons. In many instances it is the case that not only are the parts of the motor nervous system subserving the limbs affected, but also the parts connected with the face, tongue, and deglutition affected. In other words, the homologues in the pons and bulb of the anterior-horn cells of the spinal cord may be affected, and so also may the upper neurons related to the same part suffer, viz. the fibres between the cortex and the bulbar and frontal nuclei. In clinical language amyotrophic lateral sclerosis has frequently associated with it the symptoms of labio-glosso-laryngeal or bulbar paralysis.

Morbid conditions also of muscles give rise to motor paralysis. The muscles are so closely related

to the nervous system that they may almost be regarded as the lowest part of the lower motor neuron. So far as the clinical signs are concerned in one large class of muscular diseases causing paralysis—the so-called myopathies—such a conception seems quite reasonable, for in those diseases we have loss of motor power, impaired nutrition—obvious wasting, or apparent hypertrophy, due to an overgrowth of connective tissue and fat with wasting of muscular fibres—loss of deep reflexes and altered electrical reactions. In those diseases no constant change in the nervous system has been discovered, so that we are led to believe either that the changes there are such as the methods used so far have failed to reveal, or that the disease, as seems likely, is essentially one of the muscular tissue itself.

Certain other diseased conditions of muscle must be mentioned, as they cause paralysis. Such is the group of rare diseases of which the so-called Myotonia or Thomsen's disease is the type. In this condition a spasm or cramp of muscles temporarily interferes with their use. As the muscle is used the spasm disappears. The condition known as *Myasthenia* is characterised by great weakness in certain muscles, often in those supplied from the bulb, and has occasionally proved fatal. Careful examination has failed to reveal any change in the nervous system. See MYOPATHY; MYASTHENIA GRAVIS; and special articles on other forms of paralysis. JAMES TAYLOR.

PARALYSIS, ACUTE ASCENDING.—**SYNON.**: Landry's Paralysis. See SPINAL CORD.

PARALYSIS AGITANS.—**SYNON.**: Shaking Palsy; PARKINSON'S DISEASE; Fr. *Paralysie Tremblante*; Ger. *Schüttellähmung*.

DEFINITION.—A disease of advanced life; progressive in its course; and characterised mainly by tremors of the limbs occurring independently of muscular exertion, rigidity of muscles, a tendency in walking to loss of equilibrium, and a peculiar attitude of body, and fixed expression of countenance.

ÆTIOLOGY.—The causes of paralysis agitans are obscure. It is rarely met with prior to forty years of age, but becomes more and more frequent as life advances. It affects both sexes, but men probably more frequently than women. There is little reason to regard it as hereditary. It has been attributed to violent emotion, to excessive bodily fatigue, and to exposure to cold and wet. It has also been referred to wounds or injuries involving nerves. In many cases no cause is assigned or can be discovered.

ANATOMICAL CHARACTERS.—The disease, no doubt, is one of the nervous centres probably of the cortex. But no distinctive lesion has yet been discovered in these parts. Sclerotic and other degenerative changes, evidences of sanguineous exudations in the course of some of the smaller vessels, diseased arteries, and various coarse lesions, have not infrequently been met with in the cord and brain; but the morbid changes hitherto observed have been variable in seat and character, and such only as are frequently present under other circumstances in persons who die in old age.

SYMPTOMS.—Paralysis agitans, with few exceptions, comes on insidiously. The patient is first attacked with occasional tremors in a hand, a

thumb, or a foot. These attacks come on irregularly, without obvious cause, and last for an uncertain period. But gradually they increase in frequency, duration, and severity, and spread from the part first involved, until, at length, probably all the limbs become implicated. In most cases the tremors, commencing in a hand or foot, by slow degrees invade the rest of the limb, and thence spread in hemiplegic fashion to the other limb of the same side. Less commonly the affection spreads in the first instance from one leg to the other; and very rarely do both arms suffer, the legs remaining free, or does the affection involve the limbs diagonally. Associated with the tremors, sometimes preceding them, but much more frequently coming on at a later period of the disease, there may always be observed a peculiar rigidity of the muscles. This is often attended by cramp-like pains, and, like the tremors, is liable at first to more or less obvious and prolonged intermissions. It implicates the muscles of the head and neck and trunk, as well as those of the extremities, and the flexor muscles in greater degree than their opponents. Another remarkable characteristic of the disease, always developed sooner or later, is an inability to maintain equilibrium when walking is attempted.

When paralysis agitans is fully developed, and the several phenomena above enumerated are associated, the collective symptoms produce a very remarkable and characteristic picture. The tremors involve the arms and legs; the head and neck remaining, as a rule, absolutely free. They consist of fine and rapid oscillations, which are more or less constant, but liable to exacerbations; cease during sleep; can occasionally be arrested temporarily by voluntary effort; and often occur with exceptional violence when the patient is otherwise at absolute rest. The movements of the hands are peculiar. The thumbs are usually extended, and the fingers flexed upon them; and collectively they move as though the patient were rolling a pencil or crumbling bread. The oscillations, however, are not limited to the hands, but involve the wrists and other joints of the upper extremities. The tremors of the lower limbs, especially when the patient stands, are necessarily transmitted to the rest of the body. In some cases the entire head, or the lower jaw, presents tremors like those affecting other parts of the body. In rare cases the tremor may be absent, but the other striking features in the clinical picture remain. The rigidity, which affects in a greater or less degree all the muscles, imparts a striking character to the patient's attitude and aspect. It causes the arms to stand out slightly from the trunk; the elbow- and wrist-joints to be slightly flexed; the hands to be tilted towards the ulnar side, and to rest in front of the abdomen at or near the waist; and the fingers to be flexed or distorted at their several joints. It causes the trunk to incline forwards, as the patient stands or walks; the knees to be slightly bent; and the feet to be extended at the ankles; so that he rests upon his toes. But, above all, it causes the head and neck to be thrown forwards, and to be retained rigidly in that position, and the features to be immobile and inexpressive. This peculiar fixity of the head and neck and face, associated as it is with constant tremors in the limbs, constitutes a very striking feature of the disease. The difficulty of maintaining equilibrium, though no doubt increased largely by the presence of muscular tremors and rigidity, is not

wholly due to them, for it may be well developed at a very early stage of the disease. Moreover, it may be long delayed. When thus affected the patient has some difficulty in rising from his seat; and, before he starts off walking, he probably hesitates a little, as though for the purpose of balancing himself. Then, with his body bent forwards, he begins to walk, perhaps with some care, but soon his steps become rapid and short, and he runs forwards in spite of himself, and if not arrested probably falls. Sometimes the tendency of the patient is to run backwards, even though the body incline forwards. Often in these cases, while the patient is being propelled forwards apparently in spite of himself, a sudden pluck at his clothes will reverse or alter the direction of his accelerating movement. These phenomena are not attended by vertigo.

Other symptoms less striking than the above, but of more or less importance, are usually present in shaking palsy. There is generally, even from the first, a great sense of weariness in the affected muscles, especially after exertion or an attack of tremors; but, contrary to what might be supposed, the tremulous and rigid muscles are, as a rule, markedly stronger than their as yet unaffected fellows. The patient, more particularly late in the disease, becomes excessively irritable and fidgety, so that at night especially he finds it difficult or impossible to place himself in a comfortable position; he is apt also to suffer from a painful sense of heat, mainly referred to the epigastrium and back. Speech generally becomes markedly affected, not from loss of language, but from difficulty of enunciation. Words are uttered slowly, and with manifest effort. Associated with this there is often tremulousness of the tongue. But the slowness and difficulty of utterance, which are often associated with slowness and difficulty of deglutition, constitute only one manifestation of the general slowness and difficulty of movement which, for the most part, characterise the disease. Sensation is not impaired; and the patient retains his mental faculties, as well as control over the rectum and bladder, as a rule, but sometimes loss of memory and even dementia occur, as evidence of senile cerebral degeneration.

DIAGNOSIS.—The affections with which paralysis agitans is most likely to be confounded are disseminated sclerosis, and mercurial tremors. But in the former of these the tremors occur only when the muscles are in use, and for the most part involve the head; the limbs early become paralysed; the patient has no tendency to run forwards or backwards; and generally nystagmus is present. In the latter affection there is probably a history of exposure to the fumes of mercury; the tremors involve not only the limbs, but the head and neck, and are symmetrical; and there is an absence of the peculiar gait of paralysis agitans. See MERCURY, Diseases arising from.

PROGRESS AND TERMINATIONS.—Paralysis agitans is of slow and often irregular progress, and usually lasts for many years; indeed it may be many years before it attains its full development. In rare cases it is recovered from in the early stage; but for the most part it is incurable. In its last stage the patient becomes confined to his couch or bed; the muscles waste; the tremors, though generally extreme at the time, occasionally cease; the mental powers fail; bed-sores form; and general prostration ensues. Death is due either to asthenia, or to

some intercurrent disorder, more especially pneumonia.

TREATMENT.—In treating shaking palsy it is of importance to give careful attention to all hygienic measures, and to promote the patient's health, if need be, by tonics. Specific treatment has proved of little or no service. Nervine tonics and sedatives have been largely employed; and those which have found most favour probably are iron, strychnine, and hyoscyamus. The systematic use of baths has occasionally proved of temporary benefit.

PARALYSIS, DIPHTHERITIC.—See p. 402.

PARALYSIS, ERB'S.—See p. 170.

PARALYSIS, INFANTILE CEREBRAL.—

Cases of paralysis the result of cerebral disease in children may be classified in different ways. Probably the classification most generally useful is a clinical one into cases (1) in which the paralysis affects both sides of the body—cases of cerebral diplegia, and (2) in which only one side of the body is affected—cases of infantile hemiplegia. Such a classification does not of course exclude from the first class those cases in which, although both sides are affected, there is a preponderating affection of one side. The classification according to which cases of cerebral paralysis in children are divided into those in which the paralysis is present at birth, and those in which the paralysis is of subsequent onset, is scarcely a satisfactory one, for although in most cases of diplegia the paralysis is present at the time of birth, there is a certain number in which the affection is of later onset. In the present state of our knowledge it is not possible to classify these cases according to their aetiology.

1. **Cerebral Diplegia.**—See CEREBRAL DIPLEGIA.

2. **Infantile Hemiplegia.**—From this group are to be dissociated cases of hemiplegia in children occurring in the course of an acute illness, such as rheumatism or diphtheria or scarlet fever, in which the condition is one of embolism associated with the endocarditis which is so often present in these diseases. Such cases in no way differ from cases of a similar origin occurring in adults, except in so far as growing structures are interfered with and consequently individual mal-developments ensue. But cases of infantile hemiplegia proper are those which occur in the early years of life—the attacks are ushered in with an acute febrile condition almost invariably associated with unilateral convulsions, the side affected in the convulsions being that subsequently paralysed. The paralysis is of the usual type found in adults—face, arm, and leg being affected, the upper limb most obviously and severely. The subsequent condition is similar to that found at the commencement, so far as paralysis is concerned, only the paralysed limbs are found as a rule to become smaller than those on the other side. This is the result of interference with the development of the affected limbs, and cannot rightly be regarded, as it is sometimes spoken of, as atrophy. At first hemianopsia and sensory impairment are said occasionally to be present. These are never permanent. Mental impairment occurs occasionally, and epileptiform attacks frequently recur, affecting sometimes the paralysed side and sometimes

the non-paralysed side. Occasionally attacks of *petit mal* may be present, and the writer has seen such in a slightly hemiplegic patient, associated with post-epileptic automatism, in which the patient unconsciously carried out apparently purposive and often elaborate movements. Contractures, especially at the ankle, may be present, and there is usually exaggerated knee-jerk, with perhaps also ankle-clonus. The degree of mental impairment varies, but is usually slight.

Involuntary movements are frequently present; the most common is the so-called mobile spasm or athetosis, in which a cycle of slow movements is carried out in the limbs of the affected side. The upper limb is most affected, but movements may also be present in the face and in the leg. Movements of another character may also be present—short, jerky, and only evoked on voluntary movement, in these characteristics closely resembling those of disseminated sclerosis. Sometimes the movements resemble somewhat those of chorea, but the name 'post-hemiplegic chorea' has probably been applied to jerky spasmodic movements occurring on voluntary effort, such as have just been alluded to. Briefly then these cases of infantile hemiplegia differ from the hemiplegia of adults in the mode of onset—usually with an acute febrile condition and a severe convulsion or a series of convulsions—in the absence of any renal or cardiac disease, in the frequent persistence of fits, and in a not uncommon association of involuntary movements of the paralysed limbs.

PATHOLOGY AND PATHOLOGICAL ANATOMY.—Few of such cases can be examined when the condition is still recent, because few die. The subsequent condition then is one of porencephaly or of fibrosis of a part of the cortex, and these conditions are probably the result of one or other of the several morbid conditions alleged by different authorities as the initial lesion. Strumpell regards as most likely an acute inflammatory condition analogous to that occurring in the spinal cord, causing infantile paralysis (acute anterior poliomyelitis); some likelihood is given to such an hypothesis by the facts that a condition like this has actually been demonstrated in adults, and that cases of cerebral paralysis have occurred simultaneously with cases of spinal paralysis in different members of the same family. Other writers have regarded the condition as one of vascular blocking—according to some blocking of superficial veins, according to others of arteries. In some cases embolic blocking has been found, but these have been cases occurring in the course of such diseases as diphtheria and scarlet fever; and, as we have already stated, not therefore to be regarded strictly as cases of the infantile hemiplegia under consideration.

Treatment must concern itself with (a) the condition at the onset of the paralysis, and (b) the resulting paralysis, and perhaps fits. As regards the initial state, a dose of calomel should at once be administered. If convulsions are present it is necessary to administer bromide in a fairly large dose, even to a young child, and in this condition it is best given by the bowel, \mathfrak{zss} or $\mathfrak{3j}$ being administered in about \mathfrak{zviij} of warm water. Further purgation may be necessary if the convulsions persist, and if the child is not feeble and wasted. The subsequent paralysis is best treated by massage and such passive movements as will best prevent contractions and rigidity, and if con-

vulsions persist they must be treated by the systematic use of bromides. Firm discipline and educative influences of a special kind may be needed if there be some mental impairment, as occasionally happens. See IDIOCY; and CHILDREN, Training of.

JAMES TAYLOR.

PARALYSIS, INFANTILE SPINAL.—SYNON.: Acute Atrophic Spinal Paralysis; Acute Anterior Poliomyelitis; Fr. *Paralysie Essentielle de l'Enfance* (Laborde); *Paralysie Atrophique Graisseuse de l'Enfance* (Duchenne); Ger. *Kinderlähmung*.

DEFINITION.—Paralysis chiefly in the limbs and trunk, acute in onset, various in distribution and extent, followed by recovery in some parts and persistence in others, with rapid muscular wasting and the electrical reaction of degeneration; due to inflammation of the anterior grey matter of the spinal cord.

ÆTIOLOGY.—The disease is most common in children during the first five years of life; three-fifths of the cases come on in the first three years, and hence the name by which it is often known; but it also occurs in older children and young adults. In infancy, males and females suffer with equal frequency; subsequently, the affection occurs more often in males. Hereditary influences take but a trifling share in its causation; nevertheless, instances are met with in which two members of the same family suffer. Season has a marked influence; three-quarters of the cases occur during the hottest third of the year. It often follows exposure to cold, as an unaccustomed cold bath in hot weather, or exposure to a draught when heated. The exposure is usually within forty-eight hours of the first symptoms of the malady. It occasionally succeeds a fall at an interval of a few days. Over-exertion probably predisposes to it; in children this cause can often be traced. It seldom follows any different malady; in the cases in which it has been thought to be secondary to some acute illness such as rheumatism, the symptoms of this have really been part of this affection.

PATHOLOGY.—The atrophied muscles are found to have undergone granular or fatty degeneration, with disappearance, to a greater or lesser extent, of the transverse striæ. Many fibres, however, are simply narrower than normal, and occasionally some increase in width is found. Oil-globules and numerous fat-cells are also found between the fibres. Ultimately, in the most wasted muscles, fibrous tracts occupy the place of the muscular tissue, but among them a normal fibre, with its striation preserved, can here and there be seen. The amount of change in the muscles varies according to the amount of wasting. When this is moderate most of the fibres present only slight changes.

The few examinations made in the early stage have revealed a condition of acute inflammation of the anterior cornua of the spinal cord, varying in degree at different parts, but almost limited to the grey matter, extending only a short distance into the adjacent white substance. At an interval of many months or years after the onset, a condition is found such as acute inflammation would leave: there is shrinking of the anterior horns corresponding to the most affected muscles, with increase of the neuroglial tissue in them, and disappearance of many of the motor nerve-cells, most that remain being reduced to small angular bodies, among which a few are seen of normal aspect. The

corresponding fibres of the anterior roots are degenerated, and the degeneration can be followed down the motor-nerves to their fibres in the atrophied muscles. The malady is thus an acute inflammation of the motor structures of the cord with secondary acute degeneration of the fibres proceeding from the motor cells, and secondary degenerative changes in the muscular fibres, which vary in intensity according to the acuteness and inflammatory character of the descending process in the nerves. But the general disturbance, which is often so conspicuous, suggests that the local inflammation is the result of a morbid blood-state, which has a special influence on the grey matter of the cord. The rare occurrence of groups of cases in a quasi-epidemic form has suggested that the toxic agent may be derived from without. Its frequent relation to cold must, however, be remembered. In these features it may be compared to acute pneumonia.

SYMPTOMS.—At the onset of the affection there are commonly symptoms of two classes: (1) the paralysis already mentioned, which is usually preceded by (2) indications of general illness, apparently the result of a morbid blood-state—malaise, pyrexia, vomiting, headache, and rarely general convulsions such as may attend any acute disorder in early life. These vary much in amount and duration; they may be severe, and last for days before the loss of power comes on, or they may be so slight, as to be unnoticed. When severe, there is so much prostration that the process of the onset of the paralysis may not be noticed; it may be mistaken for general weakness due to the acute disease or, as is often thought, severe gastric derangement. It may only be discovered when returning strength reveals local disability. There is frequently pain in the limbs, and sometimes the pain and tenderness in the nerves is so pronounced as to justify the suspicion of a simultaneous disseminated neuritis. The pain in the limbs and nerve-tenderness usually pass away in the course of a few days, but sometimes continue for weeks, so that even passive movements cause much pain. The paralysis, as a rule, is motor only. Sensation is impaired only in extremely rare cases in which inflammation is so intense as temporarily to extend to all the conducting columns of the cord. When sensation is impaired there is always incontinence of urine, and this may be met with when there is only motor paralysis; trophic changes and bed-sores are almost unknown, even in the acute stage of the disease. A slight local elevation of temperature in the most paralysed parts has been noted in the early stage, but subsequently the affected limbs are colder than the others. This is due, at least in part, to the loss of the aid to circulation which, in health, is supplied by muscular action.

Reflex action is necessarily lost in the parts related to the muscles involved. That from the skin is at first abolished wherever there is weakness, but it returns with or soon after recovery of power in the less affected parts. If the paralysis is persistent it remains absent. The muscle-reflex action is lost in the same or even greater degree, so that, for example, no knee-jerk is obtainable if the extensors of the knee are even slightly affected. In rare cases of cervical poliomyelitis the morbid process may spread into the lateral columns, so that, in addition to the wasting and paralysis of the arms, there may be paralysis without wasting in the

legs. In such cases the myotatic irritability in the legs may be, for a time, increased.

When the paralysis of a limb is incomplete, the muscles involved vary in different cases; and as different parts of two or more limbs may be affected, the combinations of palsy which result are extremely varied. Sometimes the muscles affected are those which are functionally associated; more frequently the affection is random. The degree of affection of the individual muscles also varies, the loss of power in some being absolute, in others only partial. In the legs the paralysis is rarely complete; most frequently it is partial, and the muscles below the knee suffer more often than those above the knee. The calf-muscles are affected less frequently than the anterior tibial or peroneal muscles, and hence talipes equinus is a common form of the deformity that ensues from the contraction of the less affected muscles. Sometimes all the muscles shorten, or the calf-muscles may be chiefly affected, giving rise ultimately to talipes equinus.

In the arm any of the muscles may be involved, but all are seldom entirely paralysed. The intrinsic muscles of the hand may suffer, and either the thenar muscles or the interossei may be most damaged. The muscles of the forearm are frequently affected, but the supinators may escape when the extensors are involved. Of all the arm-muscles, the deltoid is that most frequently affected; it may suffer alone or in association with others. The 'upper-arm type' of palsy, of Erb, is sometimes met with, in which the deltoid, supra- and infraspinatus, biceps, and supinators, are all involved; but the irregularity of grouping is shown by the fact that the triceps is often affected with these muscles. The serratus magnus is occasionally affected, and the upper part of the pectoralis major (which is normally associated in function with it) may then suffer, while the lower part escapes. The middle part of the trapezius, and other of the scapular muscles, are occasionally involved. The cervical muscles are rarely affected, but the diaphragm is sometimes paralysed; permanent wasting of the intercostals and trunk-muscles is rare: both these and the dorsal muscles may be weakened at first, and more on one side than on the other. This should be borne in mind, as curvature of the spine may be produced by allowing the patient to sit up while the muscles are still weak. The muscles supplied by cranial nerves are rarely affected; but instances of facial paralysis have been recorded.

COURSE.—The course of the disease has been already indicated. There are: (1) the initial stage of paralysis, lasting for a few hours, a week, or even a month; (2) a stationary period, which lasts from a week to a month; (3) a stage of 'regression,' during which the palsy lessens and passes away, except from certain parts in which wasting occurs; this period usually occupies from one to six months; and (4) a chronic stage, during which the atrophy continues, slight improvement may occur, but contractures and deformities are developed. These are due to distortion of the articulations in consequence of the contraction and permanent shortening of the muscles that are less affected than their opponents; the former become fixed by tissue-changes in their shortened state, and by secondary changes in the ligaments of the articulations. It is especially at the foot that these occur, constituting some form of talipes, especially talipes equinus or equino-varus, less commonly talipes calcaneus. In the case of

children, the growth of the most affected limb is inevitably hindered, and in the case of the leg this may render the effect of the paralysis more obtrusive as time goes on, by its interference with the gait. It is important that the friends should be warned of this, or they will regard it as an increase in the disease.

Wherever muscular tissue remains and some voluntary power returns, this slowly improves, as the muscular tissue that remains develops under the influence of use, and complete recovery, in even the very slightest cases, is extremely rare, and, on the other hand, death from the disease is equally uncommon. If it does occur, it is in the early stage, and it may result from the initial disturbance before the nature of the complaint is recognised. Occasionally death takes place at the end of the first week or ten days, from universal paralysis, or from some profound associated cerebral disturbance. Between the two extremes every variety of degree and extent of palsy is met with, from those in which there is partial affection of all the limbs, often severe in the legs, to those in which there is only a slight affection of certain muscles in one limb.

Relapses and second attacks are almost unknown. Sequelæ are also rare, although in a few cases some other chronic affection of the spinal cord has come on when the subjects of infantile paralysis have reached adult life. Thus, progressive muscular atrophy has been observed to start from a limb paralysed by this affection. Lateral sclerosis has also occurred in adults, the subjects of old infantile paralysis.

DIAGNOSIS.—A difficulty in diagnosis is only likely to occur in the early stage, when the vomiting, which is so common, is apt to lead to the opinion that the affection is only gastric disturbance; and the pyrexia may cause the case to be regarded as a general febrile affection. The mistake can only be prevented by attention to the state of the limbs, and by giving due weight to any sign of defective power. Later, the wasting, the state of the electrical reactions in the muscles, and the loss of reflex action without any sensory change, will usually be sufficient to allow a definite diagnosis to be made. In the earlier condition, the existence of the paralysis is not unlikely to be overlooked, and the immobility to be ascribed to prostration. But total immobility, and still less local immobility, is not produced by prostration. When the pyrexia ceases, while the loss of power persists or increases, the existence of paralysis is always unmistakable. In adults the danger of a mistake in the early stage is less, but the great pain in the limbs is apt to cause an erroneous diagnosis of acute rheumatism.

From chronic diseases of the spinal cord the condition is distinguished by its acute onset. Acute transverse myelitis may be closely simulated if the inflammation of the grey matter is bilateral; the age of the patient usually suggests correctly the nature of the disease. The usual form of transverse myelitis also occurs, as a rule, not in one of the enlargements, but in the dorsal region. Difficulty will, indeed, usually be prevented by the recollection of the fact that transverse myelitis in children is always severe poliomyelitis, spreading to the white columns. The very slow onset of pseudo-hypertrophic paralysis, developing as it does gradually with the child's growth, should sufficiently distinguish it from this disease.

Cases have been mistaken for acute multiple

neuritis, especially in young adults. The error is facilitated by the conspicuous affection of the nerve trunks in severe cases; but the symptoms at the onset, the irregular distribution of the paralyses and the absence of any tendency to preponderant affection of the extremities of the limbs, are distinctive features. Diphtheritic paralysis sometimes offers a difficulty, especially if the preceding sore-throat have been slight or unnoticed, but is distinguished by its gradual onset and special features. The distinction from cerebral palsy is usually easy; in this there is never loss of faradic irritability or of reflex action, nor is there extreme or local muscular wasting. The character of the convulsions also is different; those which take place at the onset of infantile paralysis are general, those which are associated with a cerebral palsy are usually unilateral or commence locally. The mistake is only likely in cases of poliomyelitis in which the arm and leg on the same side are involved.

The only diseases outside the nervous system which may be mistaken for infantile paralysis are those in which movement is associated with pain, such as hip-joint disease, acute necrosis of the femur or the humerus, or the affection known as scorbutic rickets, in which there are symptoms of scurvy associated with those of rickets (*see RICKETS*). A careful examination is usually sufficient to show that pain alone prevents movement. The preservation of the knee-jerk is often of great significance when the legs are moved.

PROGNOSIS.—In the vast majority of cases the disease involves no immediate danger to life. This is probably greatest when there is severe constitutional disturbance, before the characteristic paralytic symptoms have been noticed. There is also some danger from after-effects, especially in consequence of the slight power of resistance to other morbid influences which remains after the severe constitutional disturbance connected with the onset.

If the paralysis has remained stationary, that is, has not increased in extent, for twenty-four hours, the danger of further extension is small. Concerning the prospects of recovery, no answer can be given for a week or ten days, and its nature will depend upon the condition found to be present on electrical examination. The muscles which then have lost faradic irritability will certainly waste, will remain for a long time paralysed, and will probably be to some extent permanently disabled. If, however, there is no loss of faradic irritability at the end of this period, but it is apparent at the end of a fortnight or three weeks, the wasting will be slighter in degree, and some ultimate recovery may be expected even in the most affected part. When there is no loss of faradic irritability, the paralysis will pass away in the course of a few weeks or, at most, a few months. But this condition is unfortunately rare.

In the chronic stage, unless there is some sign of returning power within three weeks, very little recovery will occur. The retention of voltaic irritability in the muscles is so far satisfactory as showing that there has been no destructive degeneration in them, and that there are favourable conditions for the exertion of voluntary power. But it does not lessen the grave significance of the persisting palsy and loss of faradic irritability, indicating nerve-degeneration. If, on the other hand, at the end of two or three months some faradic irritability can be detected, however slight, improvement is pro-

able, and it may be considerable. It is always necessary to remember that in children an apparently increased disability may be due, after a time, to diminished growth of a limb, and may be consistent with progressive improvement.

TREATMENT.—The treatment in the early stage should be that of febrile states generally. The child should be kept at perfect rest, as much as possible on one side, and warmth applied over the affected part of the cord by poultices or fomentations. When there is spinal pain, marked relief is afforded by these means.

Both ergot and belladonna have been credited with the power of arresting the disease, although there is no definite proof of this. Either, however, may be employed apparently without fear of harm.

When the acute stage is over, tonics, especially iron and quinine, are needed. Strychnine also may be given in all cases, but it should not be commenced sooner than three or four weeks after the disease has become stationary. As the malady frequently occurs at an age at which ricketty conditions develop from any interference with the general health, treatment with the view of anticipating such constitutional effects should be adopted in young children. For this purpose iron and cod-liver oil are especially useful.

The use of electricity is an important part of the treatment, and, in order to prevent its ineffective or harmful employment in unsuitable circumstances, the reasons for its employment ought to be clearly understood. There is no evidence that it can or does influence the process of recovery of the damaged elements either in the cord or nerves. The reasons for its use depend upon the fact that the disease entails nerve-degeneration, and that the related muscular fibres undergo changes in nutrition and ultimately perish if no nerve-regeneration occurs. While the influence normally exerted through the nerves is in abeyance, the muscles are destitute of functional stimulation, and it is with the view of supplying the place of this that electricity is to be used. When both cell and fibre have perished, electricity can do no good; but where there has been damage but not destruction, so that the fibres recover and again become capable of conveying nutritional and volitional influences, electricity is of distinct service in preventing a disproportionate failure of muscular nutrition. Only voltaic electricity can stimulate the muscles when the nerve-fibres are degenerated, and this is consequently the form that must be used. The mode of application is determined by the fact that it is only when the current is interrupted that the muscular tissue is stimulated to contract. One terminal is kept still, the other being stroked down the muscles and lifted from the skin at each stroke. Some place the immobile terminal over the spine, but there is no evidence that the spinal cord is reached in this way. The negative pole will be that most generally useful in stroking the muscles, as the normally greater irritability to the negative pole frequently persists. Of course soft terminals, well moistened with salt and water, must be used, the skin also being thoroughly wetted, and a current should be used sufficiently strong to produce visible contraction, provided this does not cause distressing pain; if it does, it is better to be content with the strongest current that can be borne without emotional disturbance. The strength used should be gradually increased, as the child gets more accustomed to the application.

Systematic massage of the affected muscles is also useful. The muscles should be rubbed and gently kneaded daily, upward rubbing being especially useful. Great care should be exercised in keeping the affected limbs as warm as possible; and bronchial catarrh should be guarded against, especially in cases in which the respiratory muscles are involved.

The prevention of deformities of the spine or in connection with contractures causing displacement at joints must be carefully looked to. Mechanical appliances may have to be ultimately adopted, and not infrequently tenotomy is necessary. But such deformities should as far as possible be prevented by systematic movement and attention to posture. The process of slow improvement, once started, may go on for years by the slow growth of the muscle that has recovered under the stimulus of use, and this improvement may be augmented by various contrivances for allowing the muscle to act to the best advantage. It is especially important to compensate diminished growth by a thicker sole to the boot, so as to prevent the tilting of the pelvis and curvature of the spine that would otherwise ensue, and to keep the foot in a natural position.

W. R. GOWERS.

PARALYSIS OF THE INSANE.—See p. 573.

PARALYSIS, PERIODIC.—**SYNON.**: Family Periodic Paralysis; Intermittent Paralysis.

DEFINITION.—An affection in which attacks of temporary flaccid paralysis with loss of electrical excitability of the muscles occur from time to time, without loss of consciousness, and in which the patient recovers completely in the intervals between the attacks.

ÆTIOLOGY.—The malady is most common between the ages of twenty and thirty, but also occurs in older and younger people. Both sexes are attacked; either may transmit the disease, and several members of a family are usually affected, although isolated cases occur. Malaria has been suggested as a possible cause, because the attacks are periodic, because some of the patients have had malaria, and because quinine has done good in some cases; the plasmodium has, however, not been found in the blood of patients suffering from attacks of periodic paralysis. Muscular exertion induces the paralysis in some cases, but in others the attacks are most frequent when the individual is at rest. Certain articles of diet appear liable to induce attacks in some patients.

SYMPTOMS.—The attacks, as a rule, begin at night; but if the patient be awake a feeling of weakness is experienced in the legs, and then in the arms and trunk. The proximal segments of the limbs succumb before the distal; but in the end there is general and complete flaccid paralysis, including the thoracic muscles, so that respiration is carried on by the diaphragm alone. The face muscles, however, as a rule escape, as do those of mastication; but these and other muscles supplied by cranial nerves are occasionally attacked.

The paralysis usually reaches its maximum in three or four hours, after which recovery takes place in about the same length of time, in the reverse order to that of the onset, the legs being the last to recover. In some cases peculiarities of physical development have been observed, such as enlargement of muscles, which, however, were not correspondingly powerful. So, too, permanent weakness

has been noted in certain groups of muscles in some patients.

During the height of an attack the muscles lose their mechanical irritability, and no longer respond either to faradism or galvanism; the tendon-jerks are abolished, and the superficial reflexes may also be lost, though this is not always the case. With return of motor power the muscles regain their electrical excitability, and the tendon-jerks can again be elicited.

The mental faculties are preserved, articulation is not defective, the appetite is often lost, but no difficulty in swallowing is experienced, and there is no respiratory distress, although the rate of the respirations and pulse may be slightly increased. The heart becomes a little enlarged, and a systolic murmur indicative of mitral regurgitation may be heard at its apex; the murmur, however, disappears as the patient recovers. Sensation is unaffected, and the sphincters also escape, though no urine or feces are usually passed during an attack.

The attacks of paralysis last, on an average, from ten to forty-eight hours; they may recur daily or the interval may be a week, a month, or even a year.

MORBID ANATOMY.—None of the cases have come to autopsy, but portions of muscle removed during life have revealed increase in the diameter of the muscle-fibres, vacuolation, and waxy degeneration.

PATHOLOGY.—The affection has been supposed to be due to some form of auto-intoxication by a poison similar to curara; but it is not easy to be certain on what the poison acts, as we know of no poison that can in the same way prevent the muscles from responding to either form of electrical current. Whether the lower neurons are concomitantly affected or not, it seems necessary to assume that the poison acts directly on the muscle-fibres. In one case a toxic substance was isolated from the first feces passed by a patient after an attack of periodic paralysis, and when injected into rabbits and guinea-pigs it caused paralysis in them which disappeared in the course of forty-eight hours. The malady has been regarded by some as related to the muscular dystrophies; but there is little to justify this view. It has also been supposed to be allied to Thomsen's disease (*Myotonia congenita*).

DIAGNOSIS.—Where history alone has to be relied on, cases may be mistaken for epilepsy or post-epileptic paralysis. On the other hand, cases seen for the first time may be confused with 'Landry's paralysis' (*acute ascending paralysis*), unless a history of previous attacks be obtained.

PROGNOSIS.—Although the duration of life does not appear to be altered by the affection, the patients, as a rule, continue liable to attacks all their lives, but in a few there has been a tendency to recovery about the middle period of life.

TREATMENT.—Beyond the fact that quinine appears to have been of some use in a few cases, nothing is known to influence favourably the course of the affection.

J. S. RISIEN RUSSELL.

PARALYSIS, PSEUDO-HYPERTROPHIC MUSCULAR.—See MYOPATHIES.

PARALYSIS, SENSORY.—See SENSATION; Disorders of.

PARALYSIS, TOXIC.—Various kinds of paralysis, due to multiple neuritis in the main, are produced by such poisons as alcohol, arsenic, and lead

on one hand; and by the poisons associated with certain specific diseases on the other, such as diphtheria, tuberculosis, variola, and others of the exanthemata. See NEURITIS, MULTIPLE; ALCOHOLISM; DIPHTHERIA; and LEAD-POISONING.

PARAMENIA (παρά, beside, amiss; and μήν, a month).—A term for irregular menses. See MENSES OR MENSTRUATION, Disorders of.

PARAMYOCLONUS MULTIPLEX (παρά, indicating on one side; μῦς, μύς, muscle; and κλόνος, commotion).

DEFINITION.—An affection, occurring in adults, which is characterised by clonic spasm in parts of the muscles of the trunk and limbs, more or less symmetrical, but varying in degree. It was first well described by Friedreich, who proposed for it this designation. Among the cases which have been since observed, there have been many variations from the type of the original case, and the malady is not well defined.

ÆTIOLOGY.—Little is known of the causes of the affection, beyond the general facts that it occurs chiefly in men, and may begin at any age between puberty and sixty years. It does not appear to be hereditary. The onset has generally been spontaneous without distinct causation; in a few cases it has followed some apparent exciting cause, such as fright, rheumatism, or malarial fever, but such cases have been too rare to suggest more than a general disturbing influence on the nervous system.

SYMPTOMS.—There are sudden spasmodic contractions of the muscles, or more commonly of parts of the muscles, causing irregular movements of the surface, but seldom of the parts to which the muscles are attached. The contractions quickly pass from one part to another. Their frequency has varied from ten to fifty per minute; but they are irregular in time, a series of quick contractions being followed by longer intervals. In some cases tonic spasm has occurred from time to time. On the other hand, very slight, and even fibrillary, contractions have characterised some cases, which have been termed 'myokymia.' They resemble those which accompany progressive muscular atrophy, of which there have generally been indications, and there is reason to regard the condition as only an excessive manifestation of the 'fibrillation' common in the early stages of that disease. In paramyoclonus the contractions are usually in the muscles of the trunk as well as in the limbs; the diaphragm is occasionally involved, causing a peculiar sound, something like hiccough. Voluntary movement lessens the spasm, and occasionally arrests it; it is also diminished by alcohol and by mental excitement. In a few cases the contractions have continued during sleep. They have been so violent in some atypical cases (possibly allied to the usual form) that the energetic spasm has thrown the patient from the chair on which he was sitting. As a rule, there have been no other symptoms in either the nervous or general system beyond hypochondriacal self-attention, which is often conspicuous and troublesome. After lasting for several months, or even for a year, the spasmodic contractions have, in some cases, gradually lessened, but the affection is so chronic that the ultimate result is often unknown. See CHOREA, ELECTRIC.

Nothing is known of the pathology of the affection. Such clonic spasm characterises the 'electric

cal chorea,' which occurs in Italy, and is probably the result of a toxic influence, possibly malarial. But this is a fatal disease, and is thus sharply differentiated from paramyoclonus. There are, however, other choreic affections characterised by clonic spasm, the nature of which is still undefined, and the severer forms of myoclonus seem allied to these. It is supposed that the clonic contractions originate in the spinal cord.

TREATMENT.—It is not clear that any treatment has modified the course of the malady, which has had a definite tendency, in most cases, either to lessen or to persist. But it has been thought that benefit has been afforded by giving bromide of potassium or hyoscine as a sedative, together with quinine, strychnine, and other nerve tonics. Voltaic electricity has been said to do good in a few instances, a current as strong as the patient can bear being passed from the spine to the affected muscles for a quarter of an hour each day. In very severe cases the hypodermic injection of morphine has been useful. The malady is so rare that therapeutical facts can only be very slowly accumulated.

W. R. GOWERS.

PARAMYOTONE (Paramyotonia; *παρά*, one side; *μῦς*, *μυός*, muscle; *τόνος*, stretching).—This name is applied to a condition characterised by muscular spasm. It is thus applicable to Thomsen's disease, a common designation of this condition being *myotonia* (see THOMSEN'S DISEASE). Two varieties of paramyotone have been described—the *congenital* by Eulenborg, and the *ataxic* by Gowers. In the former, several members of the same family were affected, and in some of these the symptoms were present soon after birth. The malady was characterised by transitory tonic spasm, easily excited by cold, and usually dispelled by warmth. The facial muscles were especially liable, and the rigidity was succeeded by weakness. There was no change in the electrical reactions, except that the irritability seemed to be lowered. In the condition of *ataxic* paramyotone, described by Gowers, there was persistent tonic spasm associated with ataxy. There was weakness both of arms and legs, but the inco-ordination was greatest in the arms. There was also impaired sensibility, distinct for touch and pain, slight for temperature, on the hands and feet, especially the palms and soles. No sign of myotatic irritability could be elicited, but the rigidity was such as to account by itself for this absence. There was no change in the electrical irritability of the muscles.

JAMES TAYLOR.

PARAPHIMOSIS (*παρά*, beside; and *φίμω*, I confine).—**SYNON.**: Fr. and Ger. *Paraphimosis*.—A morbid condition of the penis, in which the prepuce, having been drawn or forced back behind the glans, cannot be returned, and thus gives rise to a condition of strangulation of the parts in front of it. See PENIS, Diseases of.

PARAPLEGIA (*παρά*, at the side; and *πλῆσσω*, I strike).—Paralysis of the lower extremities, usually associated with paralysis of the lower part of the trunk, bladder, and rectum. See PARALYSIS; and SPINAL CORD, Diseases of.

PARAPLEGIA, ATAXIC.—The name 'ataxic paraplegia' has been given to a condition in which a lateral and a posterior sclerosis of the spinal cord co-exist. There is undoubtedly a tendency in some

cases for sclerosis to occur simultaneously in these two columns. On the other hand, such a combination with analogous symptoms may present itself in disseminated sclerosis of spinal origin, and the writer has known many cases diagnosed as 'ataxic paraplegia,' which subsequently proved to be unmistakable cases of disseminated sclerosis; it may occur also as an extension of a primary lateral, or even of a primary posterior sclerosis; whilst something very similar presents itself in Friedreich's ataxia (or 'hereditary ataxic paraplegia,' as it is also termed). More recent observations again have shown that in the remarkable affection known as 'combined sclerosis' or 'combined degeneration of the spinal cord' (see p. 325), we also have the combination of widespread morbid changes in the lateral and posterior columns. Bearing in mind, therefore, these various affections and the symptoms to which they give rise, it seems questionable whether any adequate advantage from a clinical point of view can result from the description of a separate morbid condition under the head of 'ataxic paraplegia.' It may be sufficient for us to recognise that, under the various conditions above referred to, we are liable to get a grouping of symptoms indicative of co-existing disease in the lateral and in the posterior columns of the spinal cord. See SPINAL CORD, Special Diseases of.

H. CHARLTON BASTIAN.

PARAPLEGIA, INTERMITTENT.—See NEURITIS, MULTIPLE; and PARALYSIS, PERIODIC.

PARASITES (*παρά*, upon; and *σιτέω*, I feed).—**SYNON.**: Fr. *Parasites*; Ger. *Parasiten*.

DEFINITION.—This term, in its most extended sense, is applied to those organisms which derive their nourishment wholly or in part from other living beings. See BACTERIA; ENTOMOLOGICAL DISEASE; MYCOSES; STREPTOTHRIX; TINÆÆ; and the various diseases due to animal or vegetable parasites.

PARENCHYMATOUS (*παρά*, beside; and *ἐγχέω*, I pour in).—The word *parenchyma* was formerly used to designate the connective tissue of the several viscera; but it is now applied to the protoplasm, or active elements, of a tissue or organ; and morbid processes affecting the characteristic tissue of an organ are hence called *parenchymatous*. See DEGENERATION.

PARENCHYMATOUS HÆMATOCELE.—See HÆMATOCELE, PARENCHYMATOUS.

PARESIS (*παρήμι*, I relax).—A slight or imperfect paralysis of motion. See PARALYSIS.

PARKINSON'S DISEASE.—A synonym for paralysis agitans.

PARONYCHIA (*παρά*, beside; and *ὄνυξ*, the nail). Inflammation in close proximity to a nail. A synonym for whitlow. See NAILS, Diseases of; and WHITLOW.

PAROSMIA.—See OLFACTORY SENSE.

PAROTID GLANDS, Diseases of.—See MUMPS; and SALIVARY GLANDS, Diseases of.

PASO ROBLES HOT SPRINGS, San Luis Obispo County, California, U.S.A.—Muried saline sulphur-springs. See MINERAL WATERS.

PASSIVE.—This epithet is used to express inertia. See **PASSIVE CONGESTION**, p. 301; and **PASSIVE MOVEMENTS**, p. 962.

PASTEUR-TREATMENT.—See p. 698.

PATENT FORAMEN OVALE.—See p. 657.

PATHOGENIC (πάθος, disease; and γεννώ, I give rise to).—Disease-producing. A term applied to any active cause of disease.

PATHOGNOMONIC (πάθος, disease; and γινώσκω, I recognise).—This word is associated with those symptoms and signs which are specially characteristic of a disease, and the presence of which renders its diagnosis certain.

PATHOLOGY (πάθος, disease; and λόγος, a discourse).—Pathology is the science of disease. Since there is no distinct limit between health and disease, the boundaries of this science cannot be definitely fixed. Further, the nature and character of normal or physiological vital processes are at present very imperfectly ascertained; it is therefore impossible to define those departures from the normal standard which constitute the field of pathology. As in the study of normal life it is convenient to deal separately with the structure of the body (anatomy and histology) and with its functions (physiology), so in considering diseased conditions the subject naturally falls under the two heads of Morbid Anatomy and Morbid Physiology. The term 'Pathology' is occasionally confined to this latter branch alone; at other times it is used in a still more restricted sense, as the equivalent of a portion only of this subdivision, namely, the study of the modes of action of morbid agencies. Thus, in many works on medicine, the causation (ætiology) of a disease, its morbid anatomy or underlying structural derangement, and its clinical features or phenomena of disturbed vital activity are dealt with apart from its pathology—this last term implying the mode of action of the exciting cause of the disease and the unseen effects produced by it, which have to be inferred from the phenomena manifested to one observing the sick person from without. The term 'Pathogeny' has been coined to replace this restricted sense of the term 'Pathology.'

PAU, in the Basses Pyrénées, France.—A mild, calm, sedative winter climate. Mean temperature, 42° F. Absence of cold winds; soil, gravel. See **CLIMATE**, Treatment of Disease by.

PECTORILOQUY (pectore, from the chest; and loquor, I speak).—A physical sign, connected with vocal resonance, heard on auscultation in some limited parts of the chest. The sounds of the voice in pectoriloquy are directly conducted to the ear, so that the words spoken by the patient may be distinctly recognised by the observer, as if proceeding from within the chest. See **PHYSICAL EXAMINATION**.

PECTORILOQUY, WHISPERING.—A form of pectoriloquy in which the whispered voice is heard distinctly. See **PHYSICAL EXAMINATION**.

PEDICULUS.—Three species of lice are parasitic on man: (1) *Pediculus capitis*; (2) *Pediculus vestimenti vel corporis*; and (3) *Pediculus pubis*.

1. **Pediculus capitis.**—This species of pediculus infests the head, especially the occiput; and deposits its eggs on the shaft of the hair, usually not far from the root. The ovum is a small oval, semi-transparent body, somewhat cupped at its free extremity, and very firmly attached by a short pedicle to the hair. The young are hatched in about five days. The louse when full-grown is about 2.5 mm. in length, the female being larger than the male. The head, thorax, and abdomen, which is oval, are distinct. The head is furnished with two short antennæ, and large, black, prominent eyes. Springing from the thorax are six well-developed legs, armed with strong claws, with which the animal grasps the hair. On the back of the male is seen a conspicuous, elongated, conical organ, the penis. The posterior end of the female is notched. The animal is of a semi-transparent, dirty-white colour, and is covered with short, scattered hairs.

2. **Pediculus vestimenti.**—This species closely resembles in shape and general appearance the *Pediculus capitis*, but is of larger size. It infests the underclothing, with a preference for that of a woolly kind, and it attacks and irritates the parts of the skin that are covered by clothes. The ova are generally deposited on the wool or fibre of the clothing, but occasionally on the hair of the skin as well, and the young are hatched in about five or six days.

3. **Pediculus pubis.**—This is much smaller and relatively shorter than either of the other species, and the line of separation between abdomen and thorax is less marked. The abdomen is short and rounded, which gives the animal a crab-like shape. Like the other species, it has six legs; of these the four posterior are armed with strong claws for grasping the hair. This louse infests the pubic region, and occasionally the axilla and hairy parts of the body and face, especially the eyelashes. The ova are found firmly attached to the hairs near the roots.

The different species of pediculi do not bite, as they have no jaws; but they pierce the skin or insert their probosces along the ducts opening on the surface, and draw blood by means of a sucking apparatus or *haustellum*, and in this way they derive their sustenance from the human body. Regarded in a pathological aspect, the presence of pediculi is described as a disease under the name of *morbus pedicularis*, or *phthiriasis*. See **PHTHIRIASIS**. ROBERT LIVEING.

PEDILUVIUM.—See **BATHS**.

PELLAGRA (πέλλα, the skin; and ἄγρα, a seizure).—**SYNON.**: *Erythema Pellagrosum*; **Fr.** *Pellagre*; **Ger.** *Pellagra*.—An erythema of the skin, indigenous to hot countries, and common among the peasants in Italy, Spain, and the South of France, which makes its appearance on the parts of the body most exposed to the light, especially the back of the hands, the neck, and the breast. It is accompanied by marked mental symptoms, and is believed to be due to poisonous maize taken as food. See pp. 488 and 554.

PELVIC ABSCESS.—**DEFINITION.**—An abscess situated in the pelvis and generally connected with some uterine or intestinal affection.

ÆTIOLOGY.—Pelvic abscess may result from cellulitis, peritonitis, pyosalpingitis, suppurating

ovaries, hæmatocele, or suppurative disease of the bladder or the intestine: not infrequently many of these are combined, and it is often difficult or impossible to determine its primary origin.

SYMPTOMS AND COURSE.—Pain and increased tenderness, rigors and hectic fever supervening upon the symptoms of inflammation of any of the organs above mentioned, generally point to deep-seated suppuration. As it approaches the surface the skin or vaginal mucous membrane may become oedematous.

An abscess in the pelvis conforms to the same laws as abscesses in other parts, its extension depending upon the relative firmness and tension of the surrounding tissues; it burrows in the direction of least resistance, and may open in any of the following positions: (1) Through the abdominal walls; (2) into the pelvic viscera; (3) through the floor of the pelvis; (4) through the pelvic foramina; (5) into the lumbar region; or (6) into the general peritoneal cavity. No doubt its starting-point has much to do with its subsequent course, which depends chiefly on anatomical conditions. Should an abscess open into the peritoneal cavity, which it rarely does, peritonitis ensues, and the primary disease may be lost to view owing to the gravity of the secondary lesion. Should it open into the bowel, there occurs a discharge of pus and fæces from the bowel, often of a most foetid character, especially if there be entry of gas into the abscess. An opening into the bladder may cause a long-continued cystitis.

TREATMENT.—Pelvic abscess must be treated as deep-seated abscesses in other parts of the body—in the commencement by hot fomentations or poultices, but when matter has formed it should be evacuated as soon as possible. In many cases an abscess can be punctured or incised through the vagina, and the cavity washed out with some antiseptic solution; and the low mortality and freedom from the dangers and risks inseparable from major operations should secure the employment of these methods in every suitable case. But in the majority of cases of pelvic suppuration more radical measures are required, and incision may be made either from the vagina or by the abdominal walls. The uterus and appendages may be removed or not according to the circumstances met with in different cases. The operations have been classified as follows by Sænger:—

1. *Vaginal Operations.*—(a) Anterior colpocœliotomy; (b) posterior colpocœliotomy; (c) anterior and posterior, combined with uni- or bilateral salpingo-oophorectomy; (d) colpohysterectomy; (e) colpo-hystero-salpingo-oophorectomy.
2. *Abdominal Operations.*—(a) Uni- or bilateral cœlio-salpingotomy; (b) cœlio-salpingo-oophorohysterectomy; (c) bilateral cœlio-salpingo-oophorectomy, with supra-vaginal hysterectomy.
3. *Abdomino-vaginal hystero-salpingo-oophorectomy.*
4. *Sacral or parasacral celiotomy.*

WILLIAM J. SMYLY.

PELVIC CELLULITIS.—**SYNON.** Parametritis.
DEFINITION.—An inflammation of the areolar tissue surrounding the pelvic organs both in the male and female, but much more frequently in the latter, and therefore more especially of the areolar tissue in connection with the uterus and its appendages.

ÆTIOLOGY.—Pelvic cellulitis is never idiopathic,

but always results from the invasion of the tissues by micro-organisms, most frequently streptococci, more rarely staphylococci, colon-bacilli, gonococci, and the bacilli of influenza, and diphtheria. In the great majority of cases these enter by a wound, though the gonococcus may directly penetrate the mucous membrane and invade the cellular tissue (Wertheim).

At least two-thirds of the cases are the result of childbirth. Next to this gynæcological manipulations furnish the largest number of cases; such, for example, as rough and unskilful examination with dirty fingers and uncut nails; explorations of the uterus, especially when sloughing cancer or myomata are encountered; the passage of a sound or dilators, especially sponge and sea-tangle tents without sufficient aseptic precautions; neglected pessaries, especially if dirty, rough, and badly fitting, intra-uterine stems, and vaginal tampons; and operations, either vaginal or intra-peritoneal, where the cellular tissue is exposed and infected.

It has been attributed to excessive venery, masturbation, sponges and other materials employed to prevent conception, and articles introduced for onanistic purposes. Cold is not often a cause of cellulitis, but by depressing vitality it might cause an aggravation of a parametritis previously overlooked. It has also resulted from suppuration or sloughing of myomata, hæmatomata, and hydatid or dermoid cysts; from extension of inflammation from the rectum, bladder or appendix; or from the bones, periosteum, or joints.

PATHOLOGICAL ANATOMY.—Pelvic cellulitis may be a part of a general systemic infection, or it may be localised as a parametric phlegmon. The terms malignant and benign, employed by Schroeder, would suggest that these two forms are essentially distinct; but the difference is only one of degree and not of kind, and depends upon the virulence of the poison and the resisting power of the tissues.

Parametric phlegmon commences with œdema of the cellular tissue followed by a small-celled infiltration. At first it is soft, but as the fluid is absorbed it becomes hard. It usually begins at one side of the cervix, but soon completely surrounds it, and spreads outwards into the broad ligament, separating its layers, and generally causing a bulging of its posterior aspect; though occasionally, when the lesion from which it originates is situated in the anterior part of the cervix, the anterior layer is bulged forwards. It may extend outwards to the pelvic wall, forwards to the obturator foramen, or backwards to the sciatic notch. In some cases it extends into the iliac fossa, and up to the crest of the ilium. It may cause thrombosis of the pelvic veins, and œdema of the lower extremities (*phlegmasia alba dolens*). In other cases it extends over or under Poupart's ligament to the cellular tissue of the thigh. If it extends forwards towards the bladder it may cause a paracystitis, though this is more frequently the result of suppuration or ulceration of the bladder; it may involve the cavum Retzii, and the subperitoneal tissue of the anterior abdominal wall. Sometimes it descends along the vagina (*paracolpitis*); at others it extends backwards, involving the folds of Douglas surrounding the rectum (*paraproctitis*), and extends upwards beneath the peritoneum of the posterior pelvic wall. Should suppuration occur it may form a single abscess or a diffuse purulent infiltration (*éponge purulente*). It most frequently points above

Poupart's ligament. Sometimes it passes backwards, causing extensive burrowing, and sometimes pointing at or above the iliac crest. Sometimes it escapes from the pelvis by the sciatic notch, and opens in the gluteal region. Occasionally it follows the femoral vessels into Scarpa's triangle. In others it opens into the rectum, bladder or vagina.

In chronic or cirrhotic cellulitis bands of cicatricial tissue are found, most frequently at the bases of the broad ligaments, and generally in association with deep cervical lacerations; or cordlike bands radiating outwards, upwards, forwards or backwards in the folds of Douglas (*parametritis posterior*), causing displacement and fixation of the neighbouring organs. Chronic circumscribed cellulitis is generally the result of ulceration of the bladder or rectum.

Chronic cellulitis sometimes leads to complete atrophy of the cellular tissue of the broad ligaments (*parametritis atrophicans*).

SYMPTOMS AND COURSE.—Clinically cellulitis may be divided into: (1) *Acute inflammation*, including (a) malignant form, (b) parametric phlegmon; (2) *Chronic inflammation*, which may be either (a) circumscribed, or (b) diffuse.

The malignant form is a part of acute lymphatic septicæmia (see PUERPERAL FEVER). A parametric phlegmon may in some cases give rise to very slight symptoms, perhaps merely a sense of uneasiness in the lower part of the abdomen, and may easily be overlooked. Usually, however, it commences with a sense of chilliness, seldom a pronounced rigor, followed by fever of a remittent character. The temperature rises rapidly, often reaching 102°–104° F. the first evening, falling a degree or more the following morning, and rising again at night. The pulse corresponds to the temperature, beating from 90–100 per minute with a temperature of 102° F. The patient complains of dull aching pains in the pelvis, thirst and languor. Along with these there may be obstinate constipation and pain on defecation. The urine is scanty, and there is often frequent micturition, but seldom retention of urine. The thigh of the corresponding side is often flexed. In the early stage there being only an effusion of fluid its detection is difficult; but as the phlegmon becomes harder it is easily palpated, and we become aware of a dense mass usually to one or other side of the uterus, but if large entirely surrounding the organ, which is pushed to the opposite side or firmly embedded in it. Favourable cases may recover in a few days, but generally go on for weeks before absorption takes place. Prolonged fever generally points to suppuration, but not invariably, and it may occur after an apyrexial interval attended by shivering high fever and other symptoms of the initial stage.

DIAGNOSIS.—Cellulitis has been mistaken for peritonitis, tubal disease, intra-ligamentous tumours, such as dermoids, sarcomata, hydatid cysts, intra-peritoneal hæmatomata, and malignant infiltration of the cellular tissue.

PROGNOSIS.—The prognosis in cases of ordinary phlegmon is good even when it is extensive, and when suppuration has occurred; in the malignant form, however, it is bad; and there are many cases in which it is doubtful, for example where pyæmia has developed from a secondary infection through the veins, and where an abscess having burst into the rectum its contents become putrid. Chronic

cellulitis is not dangerous to life, but the patient as a rule continues to be an invalid.

TREATMENT.—*Prophylactic* measures include careful asepsis during delivery, and in all gynaecological manipulations; and the immediate suture of cervical lacerations.

Curative.—An ice-bag applied to the hypogastrium is useful, but care must be taken not to freeze the integuments; others prefer hot fomentations or poultices. Abstraction of blood by leeching the groins, or puncturing the cervix, is not so often employed at the present time as formerly. The bowels should be freed by enemata or mild aperients, such as castor oil, calomel, or magnesia. Opium should be used with caution, but alcohol should be freely administered as in all septic diseases. The strength should at the same time be supported by easily assimilable nourishment. To promote absorption in the later stages tonics, such as iron and quinine, are advisable; also iodide of potassium. Moist applications to the abdomen in the form of a wet pack are useful, and copious injections of hot water; glycerine or ichthyol-glycerine plugs are also advisable. Where absorption has been long delayed good results have been reported from massage. Pus should be evacuated as soon as possible after detection.

WILLIAM J. SMYLY.

PELVIC HÆMORRHAGES.—Hæmorrhages in and around the pelvis may be tabulated as follows:

1. *Hæmorrhages into Viscera*: (a) hæmatocolpos; (b) hæmatometra; (c) hæmatosalpinx; (d) hæmorrhage into the ovary (follicular apoplexy).

2. *Hæmorrhage into Connective Tissue*: (a) vulvar hæmatoma; (b) hæmatoma of the broad ligament.

3. *Hæmorrhage into the Pelvic Peritoneal Cavity (hæmatocele)*: (a) diffuse hæmatocele; (b) encysted hæmatocele.

1. **Intra-visceral Hæmorrhages.**—**ÆTIOLOGY.**—(a) *Hæmatocolpos*.—When the hymen is congenitally imperforate and the ovaries and uterus normal, menstruation occurs at a somewhat postponed puberty, and the resulting hæmorrhage is pent up in the vagina. Each month this accumulation increases and becomes viscid and discoloured owing to the more watery elements becoming reabsorbed and mixed with mucus.

(b) *Hæmatometra*.—In long-standing cases of hæmatocolpos, first the cervix and then the uterus may become gradually distended with altered blood; but, as a rule, hæmatometra is produced when the vagina is blocked at the uterine end by a membranous or solid partition, or when the vagina is more or less completely absent. In such cases it is associated with distension of only the uterine end of the vagina. Hæmatometra alone is usually the result of acquired cicatricial stenosis of the cervix, or of congenital atresia of the external os uteri; and this latter is sometimes observed in a single horn of a double uterus.

(c) *Hæmatosalpinx*.—Hæmorrhage into a Fallopian tube may be secondary to hæmatometra of acquired or congenital formation. It may also be the result either of hæmorrhage into the decidua of a tubal gestation, in which case it leads either to the formation of a mole or to rupture of the tube; or of tubal menstruation with a closed uterine end.

(d) *Hæmorrhage into the Ovary (Ovarian or follicular apoplexy)*.—During the process of matura-

ion of the ovum the vascularity of the Graafian follicle is increased. This may occasionally lead to more hæmorrhage than usually occurs into the follicle either before or after the escape of the ovum, causing a much greater bulging than is usually due to a corpus luteum.

SYMPTOMS AND PHYSICAL SIGNS.—In cases of retained menstruation of congenital origin the girl will, after puberty, complain of primary amenorrhœa associated with periodic pelvic pain. On abdominal examination a hypogastric tumour may be felt, which is either a small uterus perched upon a distended and elongated vagina, or a uterus also distended with blood. On a vulvar examination being made, the hymen, or a membrane immediately adjacent to it, is seen to bulge and to become tense during forced expiration. If the membrane is thin, the dark colour of the retained blood can be observed. Examination *per rectum* will prove this fluid to be in the vagina. Sometimes one half of a double vagina and uterus is thus affected. If the uterus, or the uterus and only the upper end of the vagina are distended, a bulging *cul-de-sac* will be found *per vaginam*, and the distended portion can plainly be felt by rectal examination.

TREATMENT.—The treatment of all such collections of retained menstrual blood has to be carried out with scrupulous attention to antiseptics and avoidance of all haste or force. In cases of uncomplicated hæmatocolpos a crucial incision should be made into the bulging hymen, and the viscid fluid allowed to slowly empty itself for some hours afterwards into antiseptic gauze. The same rule should be adopted in cases of combined hæmatocolpos and hæmatometra. The greatest possible care should be taken to avoid either sudden emptying of the passages by hot or cold douches or by supra-pubic pressure, lest the uterus should be stimulated to contract suddenly and the blood should regurgitate into the peritoneal cavity. This is especially dangerous in cases of hæmatosalpinx. Absolute rest in bed for ten days in all such cases is essential. In cases of uncomplicated hæmatometra the obstruction must be dissected through and the retained fluid allowed to slowly emerge along a thin gauze drain. Subsequently, a tube may have to be worn to keep the part patent. Such uterine and high vaginal obstructions are very difficult to keep permanently open, chiefly because most of the patients with such conditions are not endowed with much mental aptitude for carrying out the requisite measures.

2. Hæmorrhages into Connective Tissue.

(a) *Vulvar Hæmatoma.*—Occasionally a pudendal vein gives way during the second stage of labour or as a result of a blow, and if the skin remains intact a vulvar hæmatoma results. Such an accident occurring during labour is commonest in primiparæ, because in multiparæ the veins are more varicose and superficial, and tend to burst externally. If a large hæmatoma is formed, obstruction to the presenting part may result.

SYMPTOMS.—The usual symptom is severe pain in one labium majus, felt suddenly during a 'pain,' in the later part of the second stage, and not infrequently 'shock' results. On examination, the swelling of the labium is found to be irreducible, dark in colour, bulging over the labium of the other side, tense and fluctuating, but gradually getting less elastic as the blood coagulates, and finally

getting boggy from œdema round the effusions. There is no impulse on coughing. It is distinguished by its history and by its physical signs from a distended Bartholini's gland, labial abscess, hernia, or varicose veins.

TREATMENT.—If there is definite, though slight, obstruction and the head presents, delivery should be accomplished with forceps. If the obstruction is such that forcible delivery would bruise or tear the swollen parts, the tumour, after the vulva has been shaved, must be incised on the cutaneous aspect, along the long axis of the labium, the clot turned out, and pressure applied till the child is born, any bleeding point being tied. If the wound can be made quite clean and free from any adhering clot, a few buried purse-string sutures will approximate the surfaces, and an attempt may be made by outside pressure to promote primary union. As a rule such cavities do not thus heal, and may be packed with gauze, and allowed to granulate up. If the hæmatoma form apart from pregnancy, rest in bed with moderate pressure will ensure absorption in two or three weeks.

(b) *Hæmatoma of the Broad Ligament.*—Hæmatoma of the broad ligament is more common than is generally thought, and one of its causes is the downward rupture of a tubal gestation, a rupture generally about the middle third of the floor of the tube. The blood is collected between the layers of the meso-salpinx—an advantageous position because considerable resistance is offered by the connective tissue of the broad ligament, and by the broad ligament itself, and the hæmorrhage is thereby generally localised. The blood may become absorbed and the pregnancy (tubo-ligamentary) continue. Another cause of the hæmorrhage is the rupture of a vein from parovarian varicocele, leading to an extravasation of blood which may be sufficiently large to produce syncope. Blows, or sexual excesses, or straining at stool or during labour, may be the exciting causes. These hæmatomata are also a common result of faulty ligation of the broad ligament after enucleation of a tumour. They are generally unilateral. Cases are occasionally seen where the hæmorrhage has spread along the back of the uterus, stripping off the peritoneum, and extending to the other side, thus simulating an intra-peritoneal hæmatocœle.

SYMPTOMS.—There is often a history of some strain, though in the case of tubal gestation the rupture may take place spontaneously owing to continued growth and thinning of the fetal coverings. There is definite shock, coming on somewhat gradually, although fairly sudden as compared with anything like the symptoms of an inflammatory attack. Pain soon follows, due to the separation and stripping off of the coverings of the broad ligament. With that follows pressure—pressure on the uterus, and indirectly on the bladder and the rectum. If the hæmorrhage is at all extensive the anæmia is well marked, but rarely is there any pyrexia, which is important in differentiating it from broad-ligament phlegmon, in which a rigor and pyrexia occur with pelvic pain.

Per vaginam there is a distinct tumour, generally rounded and at first not hard, but rapidly becoming so. The uterus is completely dislocated over to the other side, and usually fixed. The fixation of the uterus depends upon the position of the hæmorrhage. If a pregnant tube, for instance, ruptures in its middle third, there is not necessarily

a sufficient amount of hæmorrhage to reach and fix the uterus. Usually there is no exudation in Douglas's pouch, and the fact that there is a lateral tumour, and that Douglas's pouch is empty, with these symptoms of internal hæmorrhage, shows that it is not an intraperitoneal case.

PROGNOSIS.—The prognosis in these hæmatomata is generally excellent. The hæmorrhage is confined by the broad ligament: it soon ceases, and in a few weeks is completely absorbed, leaving only a patch of induration.

TREATMENT.—Recovery soon follows if the patient is kept in bed and the bowels open. If absorption, however, does not occur, it is generally for one of two reasons. Either the diffused blood has become infected from contiguity of bowel, and suppuration has occurred; or, if the hæmatoma is due to the rupture of a tubal gestation, the fœtus has remained in organic union with the placenta by means of its cord and may go on growing as a tubo-ligamentary gestation (*see* PREGNANCY, Diseases of). If suppuration occur, a small incision or puncture should be made into the swelling *per vaginam* just behind and to one side of the cervix, and the wound should be enlarged by sinus-forceps to avoid injuring the ureter or uterine vessels. The degenerated blood can then be washed out by iodised water, and the cavity be treated as an abscess, and drained carefully.

3. Hæmorrhages into the Peritoneal Cavity.—*Pelvic Hæmatocoele.*—The hæmorrhage here is intra-peritoneal.

ÆTIOLOGY.—The most frequent cause is tubal pregnancy, sometimes owing to rupture of the tube, but more commonly to hæmorrhage from the fimbriated end of the tube due to the presence inside it of a partially detached hæmorrhagic mole (missed tubal abortion). Tubal abortion may also occur, but if complete the hæmorrhage usually ceases. If a mole remains in the tube, blood may continue to trickle steadily from the fimbriated end of the tube into the peritoneal cavity. Rupture of an 'interstitial gestation' is also a cause of hæmatocoele, which is usually diffuse and rapidly fatal. Rupture of the uterus during the second stage of labour, or indeed of any abdominal vessel or viscus, may cause pelvic hæmatocoele by gravitation of blood. Hæmatosalpinx (*see* p. 1170), hæmorrhage from a ruptured ovarian cyst after torsion of its pedicle, varicocoele of the broad ligament or separation of vascular peritoneal adhesions are other less likely causes.

COURSE AND PROGRESS.—The extravasated blood may be diffused or encysted. In the *encysted* form, the hæmorrhage may from the first be slight and gradual, or it may be arrested after a short time. This would allow adhesions to be formed by lymph being thrown out round the periphery of the partially coagulated blood, and if no immediate or great strain were put upon these adhesions by a fresh outburst of hæmorrhage, the blood would become 'encysted.' Limiting adhesions are formed by the exudation of lymph and by consolidation of the outer layers of the clotting blood, glueing coils of small intestine to the fundus uteri and the mesosalpinx. Sometimes after the escape of a tubal mole, the blood and mole gravitate behind the mesosalpinx, which is dragged down by the weight of the distended tube and forms a hood over the collection of blood, and constitutes a variety of 'encystment' which, from its lateral position, is

easily mistaken for an intra-ligamentary hæmatoma. If oozing of blood into this space continues, the wall of the pseudo-cyst may give way, or the adhesions which roof over the space may stretch and give more room, or if the upper adhesions are strong Douglas's pouch may be depressed and the blood may burrow deeply between the rectum and the vagina. A hæmatocoele may also become encysted from pre-existing adhesions shutting off the pelvis from the general peritoneal cavity, as a result of antecedent perimetritis. If bleeding ceases, the cyst-wall organises and may become a definite capsule detached from surrounding viscera.

Diffused hæmatocoele is more frequently the result of a tubal rupture than of a tubal abortion or missed abortion or other source, because the loss of blood is so severe, so sudden, and so persistent, that no opportunity for its becoming localised is afforded. The diffuse form is almost invariably fatal if not treated promptly by abdominal section.

SYMPTOMS.—As a result of the visceral injury or rupture, which has led to the hæmorrhage, there is some shock, but the prominent symptoms in these cases are those caused by internal hæmorrhage. These need not be here enumerated, but are, of course, most marked in the cases of a diffuse hæmatocoele. Pain is usually a prominent symptom, and may be very severe. The mental faculties are clear. Metrorrhagia is usually present.

PHYSICAL SIGNS.—In the *diffuse* form there is some abdominal distension, but as a rule no physical evidence of the hæmorrhage is discoverable either by the abdomen or *per vaginam* except a patchy dullness here and there, not confined to the localities usually dull in ascites. The diagnosis has to be made almost entirely by the symptoms of internal hæmorrhage, by the history, which is often extremely vague, and by exclusion of other sources and positions of the blood extravasated.

In the *encysted* form the physical signs are more definite. The blood is collected so as to form at first an elastic mass, which in twenty-four or forty-eight hours gets harder, filling perhaps both posterior quarters of the pelvis and Douglas's pouch, unless limited to one side by adhesions. It is usually roofed over by intestines and omentum and mesosalpinx, and is thus confined primarily to the true pelvis; gradually if hæmorrhage persist or recur it extends upwards and may reach the umbilicus with its upper surface arched like the diaphragm. It exerts pressure upon the uterus and broad ligament in a direction upwards and forwards, upon Douglas's pouch downwards, and upon its intestinal roof upwards, so that the fundus uteri may be elevated and felt above the pubes. If hæmorrhage continue the adhesions may give way, and the hæmatocoele would then become secondarily diffuse, and if it continued and did not again become encysted, it might prove fatal. As a rule, however, the adhesions get denser, the outer layers of the blood become consolidated, and further hæmorrhage is lessened by the resulting pressure, and arrested by thrombosis in the bleeding vessels. Sometimes the temperature rises from the tension present, or fever may accompany the formation of peritoneal adhesions; or more rarely suppuration may ensue by infection from the surrounding intestines.

TREATMENT.—In the *encysted* form of hæmatocoele interference is not called for unless the temperature rises, or the tension greatly increases, or the tumour is definitely enlarging. The writer

has, under such circumstances, operated in all such encysted cases by vaginal incision (posterior colpotomy) followed by gauze-packing, with invariably good results, but cases are recorded where hæmorrhage has recurred, requiring abdominal section to remove the affected tube or seize the bleeding point. In such operations it is rare to find the fœtus or tubal mole among the blood clot, and it is not necessary to try to find and ligate the bleeding point. The hæmorrhage usually ceases at once and does not recur.

In the *diffuse* form abdominal section is absolutely and immediately necessary. If the patient is evidently losing ground, or if there has been a recurrence of hæmorrhage and it is impossible to make out a tumour definitely outlined below in Douglas's pouch and above in the abdomen, it is evident that the blood is not encysted; and in that case it becomes one's duty to operate through the abdomen at once, even if the pulse can only just be felt at the wrist. When the abdomen is opened blood wells out, and fresh hæmorrhage is apt to arise owing to reduction of pressure. The incision should be about three inches long, and no time should be lost in sponging out blood-clot. Feel at once for the fundus uteri, and, presuming the bleeding is tubal, draw the fingers along the two tubes until the lump or irregularity on the one or the other side is felt. Seize this lump and clamp the ligament on each side with Spencer Wells's large forceps, and the hæmorrhage is then entirely under control. The blood-clot, and perhaps the mole or the detached fœtus, can then be removed at leisure, and the patient rallied by a rectal or venous saline injection. Ligatures are then applied on each side of the gestation-sac, which can be removed bodily. This operation, even in apparently moribund cases, has been so often successful that it should be performed as soon as indications are absolute. It is a good plan to have the vein in the arm prepared for a saline injection by another surgeon while the abdominal incision is being made. *See SALINE SOLUTION, Infusion of.* AMAND ROUTH.

PELVIC PERITONITIS.—*SYNON.*: Peri-metritis; Pelveo-peritonitis.

DEFINITION.—An acute or chronic inflammation affecting the pelvic peritoneum.

FREQUENCY.—From the result of 600 autopsies on women Beigle found that 90 per cent. showed evidences of pelvic peritonitis; Bandl estimated its frequency as 66 per cent.

ÆTIOLOGY.—The exciting causes are micro-organisms or their products: especially septic, putrid, gonorrhœal, and tubercular infections. It is almost always secondary to disease in neighbouring organs and tissues. It frequently follows a septic metritis—the result of childbirth, abortion or intra-uterine manipulations—salpingitis and pyosalpinx. In these cases the inflammation may extend to the peritoneum either by continuity through the fimbriated extremity of the tube, by penetrating its wall, or by rupture. It may extend from the ovaries in oophoritis, abscess or tumours, especially dermoids. Pelvic hæmatocele and cellulitis are generally associated with peritonitis; and similarly inflammatory and ulcerative diseases of the bladder or intestine may involve their serous coats; the vermiform appendix especially being a fruitful source of pelvic peritonitis. Primary inflammation, the result of chill during menstruation, has been

described, but its occurrence has not been satisfactorily proved. Peritonitis has followed the injection of irritating fluids, especially a solution of nitrate of silver, into the uterus; probably owing to the escape of some of the fluid through the abdominal ostium of the tube.

PATHOLOGICAL ANATOMY.—The disease commences with injection of the blood-vessels of the peritoneum; the surface loses its lustre and becomes rough and coated with lymph. This is generally but not always followed by a serous exudation which sometimes becomes purulent or putrid. The fluid generally gravitates into Douglas's pouch, where it becomes encapsuled by the agglutination of the intestines above; and as the pouch becomes distended it forms a globular tumour which pushes the uterus forwards against the abdominal wall, the rectum backwards against the sacrum, the posterior fornix of the vagina downwards towards the introitus, and lifts the intestines upwards. In some cases where the pouch of Douglas has been obliterated by previous attacks the fluid may collect in the postero-lateral regions of the pelvis, and in others in the utero-vesical pouch. When the fluid effusion has been absorbed or evacuated, or where no fluid exudation has occurred, as is generally the case where the inflammation is due to a gonorrhœal infection, adhesion of the opposing surfaces takes place. These adhesions are found as broad surfaces, as bands, or merely as thickenings of the peritoneum. They cause fixation of otherwise mobile organs and often cause sterility or chronic invalidism.

SYMPTOMS.—As the inflammation varies immensely both in extent and severity so the symptoms may be almost imperceptible or of a most pronounced and alarming character. When the disease follows childbirth it usually sets in acutely on the second or third day of the puerperium; where it complicates salpingitis or cellulitis it develops more insidiously. It begins with a feeling of chilliness and malaise rapidly increasing to intense pain with marked tenderness. The pain is much more intense where there is a tendency to encapsulation of the effusion, and is therefore relatively a good sign. The bowels are obstinately confined with retention of flatus. There is much tympanites with rigidity of the abdominal muscles. The aspect of the patient is characteristic with sunken eyes, pinched features and anxious expression. The tongue is coated, thirst intense, and anorexia complete; generally there is vomiting and retching, often dysuria or strangury. The temperature rises gradually with slight remissions and in uncomplicated cases seldom exceeds 102° F. The pulse on the contrary rises rapidly to 120–130 or more: it is small and wiry, or in bad cases weak and compressible. The course of the disease varies according to the extent and intensity of the inflammation and the amount of effusion. Resolution is attended by a fall in the temperature, though the pulse usually remains high. Should suppuration occur, however, the fever increases and assumes a hectic character; many of the symptoms of the initial stage return; and the pain and tenderness become more concentrated towards the affected area.

PHYSICAL SIGNS.—At first the chief sign is tenderness when any part related to the peritoneum is disturbed. When effusion has taken place it forms an elastic or fluctuating tumour which

displaces the neighbouring organs in a characteristic manner. Adhesions are diagnosed by touch and by the fixation of the pelvic organs. The uterus for example may be found retroverted and cannot be replaced even when the patient is completely anæsthetised; or if replaced it immediately returns to its abnormal position. Great care must be taken in such manipulations, as injury to neighbouring organs has in some cases led to fatal results; and in no case should the uterine sound be employed. An adherent ovary, whether prolapsed into Douglas's pouch or in its normal position, can be grasped between the fingers with unusual ease and cannot be pushed about as a normal ovary could.

DIAGNOSIS.—Pelvic cellulitis is generally complicated with peritonitis, but the latter occurs very frequently without the former; it is generally possible therefore to distinguish the symptoms of both.

In peritonitis the aspect of the patient, the vomiting, pain and tenderness, are characteristic; the pulse is high and the temperature relatively low. In cellulitis the temperature is higher and the pulse not so rapid; with a temperature of 102° F., for example, a pulse over 120 would point to peritonitis, under 120 to cellulitis. The effusion and absorption of the exudation is more rapid in cellulitis than in peritonitis; in the former the exudation commences to one side of the cervix, surrounds and fixes it; the vaginal mucous membrane is pushed downwards and cannot be moved over the exudation by which it is fixed. In peritonitis the exudation is usually situated much higher in the pelvis. Lateral displacements of the uterus point to cellulitis; ante-position to peritonitis. When the vaginal mucous membrane is pushed down by a peritoneal effusion it is not fixed but can be moved over it. Such an effusion pushes the rectum backwards or to one side, but never surrounds it, and the rectal mucous membrane can be moved over it. In parametritis the rectum is surrounded and narrowed by the exudation, and its mucous membrane firmly attached to it. The relations of the posterior wall of the uterus as felt through the rectum are also important. In cellulitis the tumour never reaches above the line of firm peritoneal attachment, leaving the fundus free; in peritonitis it may reach or go above the fundus.

PROGNOSIS.—The prognosis is generally good, so far as life is concerned, so long as the disease remains localised to the pelvis; but bad as regards complete restoration to health.

TREATMENT.—In the early stage of the inflammation our objects are to favour encapsulation, to relieve pain and to support the patient's strength. With these objects she is kept as quiet as possible in bed; cold is applied to the hypogastrium by frozen compresses frequently renewed, or by Leiter's apparatus; the ice-bag can seldom be borne because of its weight. Opium is given by the mouth or rectum or by hypodermic injection; and fluid nourishment administered. A few leeches applied to the abdomen are often advantageous, but should only be employed in strong and plethoric subjects. Antipyretics are not needed and do harm by disordering the stomach, and purgatives should on no account be resorted to. When the fever has abated the absorption of the exudation should be favoured by warm compresses or poultices.

In the chronic condition efforts are often needed to free the organs from adhesions. Massage (Thure Brandt), breaking down adhesions under an anæsthetic (Schultze), or directly dividing them after celiotomy may be required.

WILLIAM J. SMYLY.

PEMPHIGUS (πέμφιξ, a bladder).—**SYNON.**: Pompholyx; Fr. *Pemphigus*; Ger. *Blasenkrankheit*.—Pemphigus is a disease characterised by the eruption of bullæ on the skin. The term has been employed to indicate almost all the forms of large vesicular or bullous eruptions, but many of these are now differentiated from the group and appear in different categories, especially in the case of dermatitis herpetiformis, and the bullous eruptions due to definite bacterial and nervous influences. There remain certain diseases accompanied by the formation of bullæ, probably of totally distinct origin, but which agree in some of their clinical characters, to which the term 'pemphigus' is specially restricted. Cases of true pemphigus must be reckoned among the rare cutaneous affections.

VARIETIES.—The following are the chief forms still described as pemphigus:—

Pemphigus acutus.—Acute pemphigus occurs less commonly than the chronic variety, but after the exclusion of vesicular and bullous eruptions due to the action of pyogenic and other bacteria, urticaria bullosa and erythema bullosum, there still remain cases which must be regarded as true acute pemphigus. The disease occurs at all ages, but is more common in children than in adults. It commences with symptoms of severe constitutional disturbance—sickness, diarrhoea, and pyrexia. The lesions vary in size from small vesicles to bullæ two or three inches in diameter, and may appear on any part of the skin; the mucous membranes may also be severely affected. The eruption appears in crops, the bullæ, at first full of serum, become turbid rapidly and show a great tendency to rupture. The skin itself becomes covered with scabs composed of the raised epithelium and a certain amount of coagulated serum. The risk of septic infection of the surface under such circumstances is great, and its occurrence has much to do with the causation of the fatal results. Cases are on record in which death has occurred in a few days, although the average duration is from three to six weeks. The prognosis depends greatly upon the amount of epithelium destroyed, as in the case of superficial burns, and is seriously affected by co-existing conditions, the most significant of which is renal disease. The majority of cases are fatal, while others recover as from an acute specific malady. The exact relations of this type of disease are not defined. For purposes of convenience the form of pemphigus arising usually in adults who have to deal with organic material, as in the case of slaughtermen, tanners, and cooks, which is often very fatal, is classified under the term 'acute pemphigus.' In these cases the probability of the inoculation of micro-organisms is very great, and in many of them the pathogenic bacterium known as the diplococcus of Demme has been isolated from the fluid in the vesicles and bullæ, and from the blood.

Pemphigus chronicus (vulgaris).—Chronic pemphigus is the most common variety of the disease and is the type of the affection. The lesions appear as minute vascular points from which rise

small vesicles. The vesicles rapidly increase in size until they reach their maturity, when they appear as bullæ of varying sizes, the majority being from half an inch to an inch in diameter, but large bullæ of three inches in diameter are by no means uncommon. These blisters have a circular or oval outline, but the border may be sinuous owing to the coalescence of two or more neighbouring lesions. The bullæ project abruptly from the surrounding skin, their walls are tense, often forming hemispherical protuberances. The contents at first are clear so that the bullæ are semitranslucent, but gradually they become turbid owing to the presence of leucocytes and the formation of fibrin in the serum. At this time a fine red areola may make its appearance immediately surrounding the bulla. The fluid contents of the bulla become rapidly absorbed, its walls become flaccid, and a thin epidermic scab remains; or if the walls rupture, its contents escape and a scab of coagulated serum and epidermic material results. The loose epidermis or the scab finally falls off, leaving a reddened or excoriated surface, the redness of which gradually gives place to a brownish pigmentation which may last for some time. Any individual lesion may pass through these changes in a few days, but the eruption comes in crops and the attacks are apt to recur, so that the disease deserves the title of 'pemphigus chronicus.'

In the case of children and old persons, the earliest symptoms are those of constitutional disturbances such as moderate pyrexia, shivering, and nausea. Simultaneously numerous small lesions may occur, running their course in a few days, succeeded by a recurrence of constitutional symptoms and of eruption. When the area affected is extensive, much discomfort may arise from the presence of the bullæ. Thus when the lower part of the back is severely affected it is difficult for the patient to assume a comfortable position, and when the excoriations produced by the removal of the epidermis are great, the patient may become greatly prostrated owing to the discomfort, sleeplessness, the effects of septic absorption, &c. A fatal result may ensue.

In the case of healthy adults, on the other hand, it is remarkable how very little disturbance to the general health appears to be caused even when the attack of pemphigus is extensive. A feeling of heat or tingling as the lesions appear, the discomfort and consequent restlessness produced by the mechanical presence of the bullæ and attempts to avoid their rupture along with slight disturbance of appetite and of the general health from confinement may be all the symptoms noted. The mucous membranes are, as a rule, not severely affected. Septic infection of the bullæ, or of the abraded surfaces, gives rise to lymphangitis and lymphadenitis with symptoms of septicæmia. In uncomplicated cases, especially if the kidneys and other organs are healthy, the disease ceases after recurrences which become gradually less and less severe, and complete recovery may occur in a few months.

Pemphigus neonatorum.—This form of disease occurs in newly born children and may be of all degrees of severity. An eruption of small vesicles may be limited to one part of the body, or the eruption may affect the whole surface. The bullæ also may vary in size within wide limits. The course of the disease varies greatly. In slight cases very little disturbance of the general health of the

infant is noted, the degree of pyrexia and the constitutional symptoms as a rule varying directly with the extent of area affected. A few reddened patches remain after the rupture or absorption of the contents of the bullæ, and a slight amount of pigmentation may remain for some time. In cases where the eruption appears over the whole surface of the body, the symptoms as a rule are very severe, and in such cases death may occur in two or three days. The whole surface is red from head to foot owing to denudation of the epidermis, in much the same way as in certain degrees of burning. In some cases, in which secondary infections may play a part, ulceration of the affected areas supervenes, and one of the forms of disease known as *dermatitis gangrenosa infantum* may be produced, leading on to symptoms of septicæmia and pyæmia.

It is noteworthy that in many cases a history can be obtained of some source of septic infection. Thus it is not uncommon to find that there has been slowness of healing or ulceration near the umbilicus, or that a scratch or injury has been noted in some part of the body. Cases are on record in which a child born of a mother suffering from puerperal fever developed pemphigus neonatorum. An instructive example is on record of the simultaneous outbreak of cases of impetigo contagiosa and pemphigus neonatorum among children attended by the same midwife. The clinical as well as the pathological evidence tends to show that in such cases there is direct inoculation of the skin with organisms, such as the *Streptococcus* or *Staphylococcus pyogenes*. Probably many examples of pemphigus occurring in individuals of greater age are of the same character. In such cases bullous eruptions may occur locally about the genitalia, on the trunk, or may be diffused over the surface of the body. In the majority of instances treatment by ordinary antiseptic measures is successful so far as the individual patient is concerned, and attention to disinfection and general hygiene is sufficient to check the epidemics of the disease which sometimes occur.

A form of the disease is mentioned in which the bullæ are flaccid and ill-formed and lead to prolonged desquamation of the type of *exfoliative dermatitis*. The exact nature of such epidemics is not thoroughly ascertained, but the accounts given point to a cause similar to that already suggested in the ordinary variety of pemphigus neonatorum.

Pemphigus contagiosus tropicus.—This is a bullous eruption occurring in very distinct epidemic form in numerous parts of the tropics. The disease may occur on any part of the body, and has many of the characteristics already described in cases of pemphigus neonatorum. It occurs chiefly during the hot weather and is distinctly contagious. The skin is liable to be specially affected where surfaces are in contact. As the bullæ heal, circinate rings of crusted eruption are left for some time, closely resembling the appearances produced in certain cases of impetigo contagiosa (p. 724). Micrococci have been observed in the contents of the bullæ, usually as diplococci or in groups. From the description given of the disease, there can be but little doubt that it is closely allied in ætiology to the form of pemphigus just described as pemphigus neonatorum.

Pemphigus foliaceus.—This disease is one of the forms of dermatitis which becomes universal in distribution, producing general exfoliation. Its

relations to the other varieties of pemphigus are obscure. As a rule the attack commences as an outburst apparently of pemphigus chronicus. After the first onset the typical appearance of the disease is assumed; the bullæ which form are flaccid; their contents lose their translucency and become sero-purulent; their epidermic coverings are detached and expose the underlying excoriated surface, which remains moist and continues to exude a sero-purulent discharge, often of extremely offensive nature. The tendency to the formation of bullæ becomes less and less marked, and the epidermis exfoliates till at length the appearance of general exfoliative dermatitis is closely simulated. The tendency for the altered epidermis to crack and emit sero-purulent fluid and blood remains to a greater or less extent, so that septic absorption from the surface is a constant source of danger. The disease, which may be at first local, tends to become universal, affecting the hands, feet, scalp, and body generally. The nails become distorted, roughened, and may atrophy and disappear, while the hair is either shed or becomes irregular in its growth. The eyelids become inflamed and everted, great discomfort being thereby produced. The mucous membranes of the mouth and throat are affected, the epithelium being thrown off after the appearance of irregular and deformed vesicles. The pyrexia and constitutional disturbance vary greatly. Usually the temperature ranges above the normal with frequent exacerbations of fever. The disease, though almost invariably fatal, is characterised by remissions and exacerbations. During the period of remission the skin may show great improvement and the general condition of the patient improves. Gradually the discomfort and pain, and the effects of septic absorption, undermine and destroy the health of the patient, till at length a condition of severe toxæmia is produced, associated with a low form of delirium, and death occurs from exhaustion. Long before the final result, the difficulties in nursing and feeding the patient become excessive, while the risk of intercurrent disorders of viscera, especially the lungs and kidneys, or of pyæmic accidents is great.

Pemphigus vegetans.—This is one of the rarest of diseases of the skin, but seems to be widely distributed. After a variable period of illness, bullæ, resembling those of pemphigus foliaceus, appear on the hands, feet, axillæ, groins, and the buccal mucous membrane; subsequently other parts of the body become affected. On rupturing, the bullæ do not heal up, but the skin tends to remain raw and even to ulcerate. On the excoriated surfaces granulation-tissue appears in some places producing fungating growths, in others an appearance resembling condylomata. The disease appears to vary greatly in severity, but cases which become widely spread cause most serious debility, and are nearly always fatal within comparatively short periods. In all probability the specific cause of the disease is different from the forms of pemphigus already mentioned.

HISTOLOGY.—The descriptions of the microscopic appearances in the disease vary mainly in the definition of the exact place of origin of the bullæ. According to some observers the collection of fluid makes its appearance at the upper margin of the stratum mucosum, raising above it the stratum corneum, and perhaps a few adherent cells of the stratum mucosum, while others describe the bulla

as commencing in the lowest layers of the rete, raising above it as it collects the whole of the epidermis. No doubt both conditions occur and depend upon the nature and severity of the form of the disease. The serum, at first translucent, gradually contains more and more leucocytes, which pass in from the underlying vessels of the corium, so that the bulla appears turbid and its contents are sero-purulent. A certain amount of fibrin may also be observed in the bulla, frequently containing leucocytes in its meshes; epithelial cells, singly or in groups, may also be present in the vesicle. The changes in the cutis are those of a mild degree of inflammation with congestion of the blood-vessels and widening of the lymph-spaces. The exudation of round cells into the cutis, slight at the commencement, becomes denser as the bulla becomes turbid, the papillæ flattening or swelling owing to the pressure of the fluid from above, and the oedema and infiltration of leucocytes from below. As a rule, the round-cell infiltration becomes absorbed so that very little damage is done to the cutis. Visible cicatrix indeed is rare as the result of uncomplicated pemphigus. In cases of pemphigus foliaceus, and in cases of chronic pemphigus of long duration, changes consisting of condensation of the cutis and atrophy of the epidermis, resembling those found in general exfoliative dermatitis, become evident. The changes in pemphigus vegetans, on the other hand, are completely different in character as the disease affects the mesoblastic structures of the skin rather than those derived from the epiblast.

BACTERIOLOGY.—The bacteriology of the disease has been studied carefully; but the results are not as yet decisive. In some of the cases the contents of the vesicles seem sterile; probably in the majority cocci, resembling the *Staphylococcus epidermidis albus*, may be seen in the contents of the vesicles. In later stages of the disease the white and yellow cocci of suppuration and other organisms are found present. Such results are especially to be expected in the class of cases belonging to the type of pemphigus neonatorum and pemphigus contagiosus tropicus. In certain severe cases of the disease a diplococcus described by Demme has been frequently isolated, and has been suspected of being the principal factor in its causation.

TREATMENT.—Taking pemphigus chronicus as the type of the disease, the treatment during its course should be of a palliative character. Owing to the sensations of heat, pruritus, and irritation characteristic of the first period of this eruption, sedative and astringent lotions containing glycerine of subacetate of lead, calamine, oxide of zinc, lime-water and glycerine are of much service. The use of dusting powders, of starch, oxide of zinc, and siliceous earth, with the addition of boric acid, camphor, menthol, &c., in varying strengths are often of much use on account of the relief to pruritus which they afford. Special care must be taken to protect the bullæ, and to prevent septic inoculation of their contents, or of the denuded surfaces remaining. As a general rule the bullæ should not be opened artificially, but when they occur on situations where accidental mechanical injury is certain, they should be opened with the point of a fine knife, taking precautions against the introduction of pyogenic organisms. The surfaces should be carefully and frequently dressed with antiseptic applications, such as boric-acid ointment, &c. No internal remedy has been definitely shown to have

a specific effect on the treatment of the disease. The drug which has been most widely used is arsenic, and by some this remedy has been vaunted as specific, but it does not occupy this position, and it is doubtful whether it has much beneficial effect. It is certainly capable of producing much harm when given during prolonged periods, and in large doses, as used to be the custom. Benefit may perhaps be expected as the result of administration of internal antiseptic remedies, such as quinine, salicin, &c. With our present knowledge, however, internal treatment consists in taking precautions to sustain the general health by appropriate food and tonics.

In cases of Pemphigus neonatorum, Pemphigus contagiosus, &c., in which the evidence of inoculation of the skin with organisms allied to the ordinary pyogenic organisms is almost complete, the use of stronger antiseptic remedies to the surface is urgently indicated. The rapidity with which bullous eruptions of severe degree of this type are seen to vanish under such treatment and their non-recurrence are strong indications of their etiology. As an external antiseptic the best remedy is mercury. The affected surfaces may be bathed in weak solutions of the perchloride (1-2000 to 1-10000) while the excoriations or bullæ as they collapse are dressed with the diluted ointments of nitrate of mercury or of ammoniated mercury. In the cases where the application of mercury may give rise to danger from absorption of the drug we must content ourselves with the use of less powerful antiseptics. The type of these is boric acid, but many remedies of the organic series, such as carbolic acid, lysol, chinolol, and iodol, have proved very serviceable. In cases of general exfoliation and pemphigus foliaceus, the severity of the disease and its depressing power render it necessary to make still greater exertions to sustain the health of the patient and to protect the epidermis from every form of injury. Careful and repeated dressing of the surface with soothing and antiseptic lotions, ointments and dusting powders must be employed. Good results from the use of warm baths made with gluten, bran, or alkalis, according to the necessities of the case, are frequently obtained. In certain cases the patient finds his only relief from suffering while immersed in such a bath. With due precautions he may remain in the bath for hours at a time, while cases are on record of patients remaining in the bath during periods of weeks, arrangements for retaining a suitable temperature having been made. The risks of an intermittent bath are the chances of chill to which such patients are exceptionally liable, and the injury to the skin owing to the alternations between constant soaking and drying. In cases of pemphigus vegetans the granulomatous character of the lesions demands carefully applied antiseptic treatment, owing not only to the risk of septic contamination, but also to the depression produced by the absorption of septic matter from the surface and the great fetor thence arising.

The care of severe cases of pemphigus, on account of the chronicity of the disease and the serious nature of the symptoms, is a most responsible task, and requires the utmost care and patience on the part of both nurses and medical attendant.

JAMES GALLOWAY.

PENIS, Diseases of.—**SYNON.** : *Maladies de la Vergé* or *du Penis*; *Krankheiten der Ruthe* or *des Penis*.—In this place will be described the

following conditions: (1) congenital abnormalities; (2) phimosis; (3) paraphimosis; (4) adherent prepuce and preputial calculi; (5) inflammation of the penis; (6) gangrene of the penis; (7) herpes preputialis; (8) benign growths; and (9) malignant disease of the penis.

It will be sufficient to mention the occurrence of—double and triple penes (generally no urethra), too large a penis, small genitals, fracture, dislocation, hematoma, and fistula (congenital and inflammatory) of the penis. The remaining diseases of the component parts of the penis will be found in the several articles upon these special subjects, such as diseases of the urethra, chordee, gonorrhœa, gleet, balanoposthitis, syphilis, and priapism.

1. Congenital Abnormalities.—There are two chief abnormalities—(1) hypospadias, and (2) epispadias.

(1) *Hypospadias* is much the more common of the two. It consists in a deficiency in the floor of the urethra. The cause is the failure of union of the two sides of the 'genital groove' which is formed in the mesial line of the genital eminence. It is by the coalescence of these two ridges that the scrotum, floor of the bulbous and penile urethra, the frænum and lower part of glans and prepuce are formed. The membranous and prostatic urethra is formed by the union of the urogenital sinus with the allantois, the urogenital sinus being cut off from the anus by the growth downwards of the transverse fold of the perineum. The extent of the deficiency of the union varies considerably in different cases. (a) There may be a want of development of the frænum only, leaving a very large meatus urinarius and perhaps a large cowl-like prepuce. (b) There may be a complete fissure from the meatus to the scroto-penile junction, or along any part of this distance. (c) There may be a fissure extending the whole length of the urethra from the meatus to the triangular ligament separating the testicles into their respective compartments of scrotum. This is one form of so-called 'hermaphroditism,' the external genitals simulating the female character. Besides these three chief forms there are many curious deformities of the meatus and fossa navicularis which are formed by the depression of the epiblast as a blind pouch, which joins the main urethra before birth. For example, there may be a persistence of this pouch, the real urinary orifice being placed in the position of the frænum, or further back along the inferior surface of the penis; the meatus under such conditions is generally very small. The writer recently saw a case in which there was a double urethral opening at the meatus urinarius. The upper one, an inch long, was blind; the lower one led into a contracted fossa navicularis, and through it urine was passed. Rarer abnormalities are the opening of the urethra into the rectum, or through the perinæum, or through the penile floor at any point, the remainder of the urethra being a solid fibrous cord.

(2) *Epispadias*.—This rarer condition is apparently a deficiency of the dorsum of the penis, in which the floor of the urethra is more or less exposed from the meatus urinarius backwards. The actual condition is really that of hypospadias, the penis being rotated upon itself in its long axis, so that the un-united genital furrow looks upwards, and the corpora cavernosa look downwards; the direction of the rotation, either from right to left or left to right, is often quite obvious at the root of the

penis. There are two chief varieties: (a) partial, in which the deficiency is limited to the penis; (b) complete, in which the deficiency extends backwards and joins with an extroversion of the bladder, the mucous membrane of the bladder being directly continuous through the abdominal wall with the skin-like lining of the genital furrow on the dorsum of the rotated penis. In both hypospadias and epispadias the prepuce is generally large and loose, and often arranged in a fold on either side of the glans and the congenital furrow; there is no properly formed frænum; the floor of the urethra and the surrounding structures are very dense and fibrous, owing to the presence of much scar-tissue in them.

SYMPTOMS.—In slight cases there is only inconvenience in the position and method of passing urine. In the more serious cases the symptoms may be placed under two headings, sexual and urinary. (1) Sexual intercourse is impossible, painful or defective, since the penis is very small or curved in various directions by the bands of scar-tissue; erections are generally painful on this account, and semen is not properly introduced into the vagina owing to the position of the urethral orifice. (2) In bad cases urine is constantly dribbling away, causing soreness, a foul odour, and general disgust. This is the greatest misfortune in complete epispadias. From these causes the general health deteriorates considerably.

TREATMENT.—In slight cases no treatment is necessary, but in the more severe cases the condition of the patient is so terrible that a surgical operation should be performed. The results are not very satisfactory. The operation should be performed after puberty, if it be possible to wait. The wearing of a special apparatus is sometimes useful in alleviating the sufferings of the patient.

2. **Phimosis.**—Phimosis is a constriction of the orifice of the foreskin which limits or prevents its retraction.

There are two varieties, congenital and acquired. (1) *Congenital phimosis* is extremely common. The orifice of the prepuce of the newly born infant is often constricted in varying degree, and may be as small as a pin-point. (2) *Acquired phimosis* comprises three conditions of common occurrence. (a) Inflammatory phimosis, in which swelling of the foreskin (which may have a normal or a slightly constricted orifice) prevents its retraction; (b) that condition in which previous inflammation and ulceration have produced sufficient scar-tissue in the orifice of the foreskin to prevent its retraction; and (c) many cases of warts, cancer, and other diseases in which the implication of the prepuce produces a similar result.

SYMPTOMS.—The presence of phimosis renders cleanliness of the penis an impossibility, as smegma and urine collect underneath the foreskin. The resulting accumulation of filth may produce itching and irritation, and suppurative and ulceration may ensue. From this cause children are continually pulling at the foreskin, which becomes very long. This habit is likely to engender the pernicious habit of masturbation, and is occasionally mistaken for a symptom of stone in the bladder. As a predisposing cause of gonorrhœa and syphilis, phimosis is a most important factor; any discharges which enter the orifice of a phimosis have an excellent situation for developing disease in its most virulent form, since there is deficient drainage, an ample supply of food for the growth

of germs, and a soft delicate mucous surface which is easily damaged. The stream of urine is diminished in size and urination is slowed, and the foreskin is sometimes distended by the outflowing urine. In bad cases there may be retention of urine with dribbling incontinence from the overflow, the patient enduring the greatest suffering and distress. This condition is often accompanied by convulsions in children. Straining in phimosis frequently induces hernia. In a perfect phimosis the glans penis is very small, the frænum very short, and the urethral orifice very small or closed entirely, another meatus existing elsewhere as in hypospadias. Secondary diseases of the bladder and kidney may ensue from back-pressure and infection resulting from phimosis. The irritation of a bad phimosis in children is liable to produce symptoms suggestive of hip-joint disease. Cancer of the penis is very rarely seen in the circumcised.

TREATMENT.—In cases where the constriction is not well marked it is possible by drawing the foreskin back a little more each day to stretch the orifice until it will completely retract. Care should be taken to keep the parts very clean and very dry during these exercises, and to replace the foreskin immediately after retraction, or paraphimosis may ensue. In cases where the constriction is well marked (such being the majority) circumcision should be done at once. In those cases where phimosis is complicated by swelling, discharge, inflammation, ulceration or chances of the glans or foreskin, circumcision should be done immediately and under the strictest antiseptic precautions. If the operation be performed as described below, and if the patient be under the influence of mercury, circumcision may be done for hard chancre, the wound healing well without the development of syphilitic ulceration in the operation-wound.

Circumcision.—If the patient be an infant or a nervous adult a general anæsthetic is necessary, but in an adult patient with no inflammation of the parts, β -eucaine is quite sufficient (see *ANÆSTHESIA, LOCAL*). Fill a hypodermic syringe with boiled solution of β -eucaine containing 2 grs. of the drug, insert the needle in the subcutaneous tissue at the root of the foreskin opposite the root of the frænum, inject a small quantity, then pass the needle in a circular direction around the coronal-preputial junction, injecting a little into the subcutaneous tissues all the way. The foreskin is then pulled on to the needle in the distant semicircle of its extent, so that the needle completes a circle around the root of the foreskin. Wait a short time, then pull the foreskin forwards, clamp its base obliquely from above downwards and forwards, and cut off sufficient skin. Slit up the mucous membrane, remove it with scissors, leaving a short frill at its attachment, the frænal mucous membrane being left long on each side. Now carefully stop every bleeding point by fine catgut ligatures, then sew up by many separate stitches; absolute approximation of the edges should be achieved. The best stitches are fine horse-hair, one end of the knot being left an inch long. If all hemorrhage be stopped and absolute approximation of edges be achieved healing by first intention with no pain is assured. The long black stitches are easily removed on the seventh day. The best dressing for an infant is a narrow strip of butter-cloth covered with eucalyptus-vaseline. For an adult no dressing is needed except a little antiseptic powder. Patients need not stop in bed more than

twenty-four hours. In clean dry cases the penis should be kept in the vertical position. In septic cases ordinary fomentations and dressings should be employed for a day or two.

3. **Paraphimosis.**—When the foreskin has been retracted and cannot be drawn forwards again, the whole of the red portion of the prepuce swells enormously. The glans penis is also swollen, but to a less extent. This characteristic appearance, called paraphimosis, is caused by the retraction of a foreskin with a small orifice either during copulation or otherwise; or it is caused by the retraction of an inflamed prepuce with a normal orifice, in which case the swelling of the foreskin from inflammatory exudation and oedema prevents its replacement. There are two classes of cases. (1) In the first group there is little pain with no inflammation, ulceration, or discharge from the parts. Under these circumstances, as the swelling is only an oedema, the penis should be fixed in the vertical position, and kept clean and dry. The swelling will slowly subside, leaving the penis with all the advantages of a circumcision. (2) Those in which there is a large amount of swelling from oedema and inflammation of the prepuce. In these cases there is acute suffering, and generally a discharge of pus. Gonorrhœa, syphilis or septic ulcers are also frequently present. If the constriction last a day or two, there will be a slough of the constricting ring (the preputial orifice). This slough starts on the dorsum at the bottom of the deepest crease.

TREATMENT.—Reduction should be effected immediately. Wind a piece of narrow elastic webbing around the glans penis from the meatus to the corona, and then on to the swollen red surface of the foreskin, remove the webbing quickly, apply vaseline to the glans penis, and then firmly press the glans through the constriction with the two thumbs. A piece of bandage placed loosely around the penis gives a good circle of counter-pressure. If this method fail, the constricting preputial orifice should be divided on the dorsum with a tenotome. The deepest and tensest constriction should be found: this is generally in the posterior crease. If there be gonorrhœa, chancres or other ulcers present, the best treatment is circumcision (*see* PHIMOSIS). After reduction apply lead and opium or antiseptic fomentations. Elevate the penis to the vertical position, and fix it by bandages around the waist.

4. **Adherent Prepuce.**—In many cases of phimosis there is some adhesion of the foreskin to the glans penis. This condition intensifies the misfortunes of phimosis, and if the adhesion be universal it will greatly retard the growth of the glans. In many cases the adhesions are only small and localised.

In the slighter cases retraction of the foreskin will stretch the adhesions sufficiently, but in the more severe cases circumcision should be performed. In this operation the adherent surfaces must be thoroughly separated by the handle of the scalpel, or if it be necessary by actual dissection.

Preputial Calculi.—In rare cases the secretion of the glandulæ odoriferæ around the coronopreputial junction collects in large quantities, forming calculi under the foreskin. These stone-like masses consist of lime-salts and organic matter. Occasionally they grow to a very large size. The treatment consists in circumcision. *See* p. 335.

5. **Penis, Inflammation of (*Penitis, Cavernitis*).**—A rare condition caused by severe injury or severe venereal disease. Cases have been recorded in the acute specific fevers, gout, and diabetes. Treatment is conducted on general principles.

6. **Penis, Gangrene of.**—A rare condition except as an extension of gangrenous ulcers of venereal origin, or from constriction by ligatures, rings, &c. Cases have been recorded of gangrene of the penis in the acute specific fevers. Death commonly results in the latter cases.

7. **Herpes Preputialis.**—This is a common complaint consisting of an outbreak of a crop of vesicles on the prepuce or skin of the theca. It is an ordinary acute vesicular dermatitis produced by septic discharges or by friction against the clothes, or in copulation. It recurs again and again. It is a very important point to diagnose this simple condition from more serious diseases, as it often causes great mental distress to the patient, who thinks that he has become inoculated with syphilis or other venereal disease.

The parts must be kept clean and dry, and lead-lotion applied. To prevent recurrence bathe the prepuce and glans with spirit-lotion or a solution of alum, in order to harden the epithelium. *See* HERPES PROGENITALIS.

8. **Benign Growths.**—The skin of the penis is liable to any of the ordinary diseases of the skin. The penis itself is very rarely affected by benign growths. The glans penis is sometimes the seat of a naevus, but the common benign growth of this region is the *papilloma* or *venereal wart*. The writer has seen a case of a huge dense fibroma involving the glans and the three corpora of the penis as far back as the pubis. It had been slowly growing for many years and was causing a pressure-stricture of the urethra with chronic retention. It was very pale in colour, hard, dense, and horny to the touch.

Papillomata are very common on any part of the penis or in the urethra, on the abdominal wall, thighs, perineum or anus. They may be associated with urethral discharges, but often they are not so associated, the penis being quite dry. They are infectious, they grow very rapidly and they do not infect glands. They may be small and dry or marvellously exuberant in growth, covering huge areas, red and fungating in appearance, pedunculated or sessile. They are soft growths infiltrating the skin only in their immediate bases. The discharge may be serum, blood, or pus. When they suppurate the stench is abominable. When they are moist the areas grow rapidly and will affect an opposing surface by inoculating it.

TREATMENT.—If the warts be small and dry, keep the parts clean and apply resorcin-powder. Cauterising with pure carbolic acid or ethylate of sodium is also useful. If the warts be large and pedunculated, inject a little β -eucaine into the skin and snip off the wart and its base by sharply curved scissors. Afterwards keep the wounds clean and dry with resorcin or some antiseptic powder. In bad cases the patient must stop in bed and, under a general anæsthetic, the whole must be removed by a superficial dissection of the warts and their bases. In very extensive cases the condition has to be dealt with in sections at different times.

9. **Penis, Malignant disease of.**—There are two varieties of malignant disease of the penis,

epithelioma and sarcoma. The latter is very rare, and occurs in the corpora. *Epithelioma* is a common disease, starting on the prepuce or glans penis as a pimple, wart, fissure, or hard nodule. It is a squamous-celled epithelioma. The apparent cause in many instances is the presence of a phimosis, under which irritant secretions have collected. Epithelioma is very uncommon in the circumcised. It occasionally starts from tertiary syphilitic ulceration of the penis. It is seldom found before the age of forty, the commonest period being from fifty to seventy years of age. There are two varieties of this disease. (1) The excrecent or papillary form is a large cauliflower-shaped mass of papillary growth, red, fungating, bleeding easily, discharging foetid pus. This outgrowth arises from a hard stony mass of infiltration in the glans or prepuce, its edges everted and very hard. (2) The excavating or cavernous form, in which a cavity is formed, has a stonily hard base with infiltration of the surrounding tissues, and a warty floor. It discharges a foul sanious serum or pus. In both varieties of the disease the superficial oblique inguinal glands are soon affected, and as the disease progresses into the corpora penis the iliac and lower aortic glands become epitheliomatous. The progress of the disease is somewhat slow at first, but more rapid when the corpora are involved. In the cavernous variety the disease progresses more rapidly than in the papillary, the amount of infiltration being greater in the former. As the disease advances it destroys every structure, ultimately forming a huge ulcer involving the penis, scrotum, and surrounding skin, the urethra opening as an ulcerated orifice upon it. If there be phimosis the ulcer will be hidden for a time until it ulcerates its way through the prepuce, producing multiple holes. The general symptoms of cachexia, wasting, &c., are well marked.

DIAGNOSIS.—This is not difficult in the majority of cases, but in a man over forty a chancre, gumma or ulcerating wart may be mistaken for cancer. In warts there is no infiltration of the skin or involvement of glands. In chancre and gumma (which may have existed for months) the surrounding tissues are hard and the glands in the groin may be very large and indurated. In the chancre there will be some signs of secondary syphilis in the throat, skin and other glands. In the gumma the diagnosis is often very difficult. Previous history of syphilis, the exhibition of iodide of potassium, and the microscopical examination of a piece of the tissue will confirm the diagnosis. Gummatous ulceration of the prepuce, glans and urethra are more common than is generally supposed. The writer has seen many more cases of gumma than of epithelioma.

TREATMENT.—The whole of the disease should be removed by operation. Either partial or total amputation of the penis and complete removal of the enlarged glands on each side is necessary. If the disease should have involved abdominal glands operation is not justifiable unless there is great suffering from pain, soreness, or the foul odour of the ulcer. In those cases in which the primary disease is very extensive and the secondary glandular involvement has spread to the spermatic cord or to the femoral vessels and anterior crural nerve, no operation will effect any improvement in the patient's condition.

Penis, Elephantiasis of.—See FILARIASIS.

CHARLES GIBBS.

PENTASTOMA DENTICULATUM.—The larval form of a member of the class Arachnida (*P. tenioides*). The adult form is met with in the nasal cavities of dogs, while the larva usually infests the liver of herbivorous animals; rarely it occurs in this organ in man, and still more rarely in the lungs, spleen, intestine, and kidney. Its body is 4 to 5 mm. long, and 1·5 mm. broad; it possesses about nine segments, with spiny margins. The mouth is surrounded by four hooks, with chitinous sheaths. Remnants of the larva, usually hooklets, are occasionally found *post mortem*, embedded in cretaceous nodules the size of peas. This parasite does not give rise to symptoms of disease in man, but may bore into the peritoneal cavity in lower animals and give rise to peritonitis. The mature form has been met with in the nostrils of a human subject. J. BLAND SUTTON.

PEPTONISED FOOD.—This term may be used as the equivalent of the phrase 'artificially digested food.' In natural digestion albuminoid substances are changed into peptones, and starchy matters into dextrin and sugar. These processes are of a purely chemical nature, and they can be imitated outside the body very closely by means of artificially prepared digestive juices. An extract of the stomach, or of the pancreas, in water, has approximately the same powers as the natural secretions of those organs. Hence it is possible for us to subject articles of food beforehand to complete or partial digestion; and to administer such artificially digested food to our patients. In cases where the natural digestive powers are more or less in abeyance, it is an obvious advantage to be able to give food thus modified.

Methods of Preparation.—Peptonised or artificially digested food may be prepared, either by following the gastric method with pepsin and hydrochloric acid, or by following the intestinal method, and using extract of pancreas. The latter method yields by far the better results. The pancreas acts not only upon albuminous substances, but also upon starch. Pepsin, on the other hand, is quite inert in regard to starch. Moreover, the products of artificial digestion with pepsin and acid are much less agreeable to the taste and smell than those produced by pancreatic extract. By the latter method articles of food can be profoundly peptonised with little deterioration of that agreeable savour which makes them inviting to the palate. This article will, therefore, be confined to the pancreatic method, and the modes in which food may be partially digested beforehand, and yet constitute an acceptable nourishment for invalids.

The first necessity is to procure an active extract of the pancreas. Water is the proper solvent of the digestive ferments; but, in order to obtain a stable preparation, some preservative agent must be added to prevent decomposition. A mixture of one part of rectified spirit with three parts of water answers every purpose. The pancreas of the pig yields the most active preparation; but the pancreas of the ox or the sheep may be employed, if that of the pig is not obtainable. The pancreas of the calf also yields an extract which is active on albuminous substances, but it is not active on starchy materials. In procuring a supply of pancreas from the butcher, it is well to remember that the word 'sweetbread,' which is the English vernacular for pancreas, is likewise applied to the thymus gland; and that the

genuine sweetbread of the kitchen is the thymus of the calf. Butchers distinguish the true pancreas as the 'liver-' or 'stomach-bread.' Liquor pancreatis is an official preparation. It is made from the fresh pancreas of the pig, freed from fat and external membrane, and ground up with washed sand or pumice-stone. To each part, four parts of 20 per cent. alcohol are added and the mixture is filtered after macerating for seven days. The dose is 1 to 2 drachms.

Directions for the Preparation of Various Kinds of Peptonised Food.—The articles which are most easily prepared, and are most likely to be serviceable to invalids, are the following:—

Peptonised Milk.—A pint of milk is diluted with a quarter of a pint of water, and heated to a temperature of about 140° F. Should no thermometer be at hand, the diluted milk may be divided into two equal portions, one of which is heated to the boiling-point and added to the cold portion, when the mixture will be of the required temperature. Two teaspoonfuls of the liquor pancreatis and ten grains of bicarbonate of sodium are then added to the warm milk. The mixture is poured into a covered jug, and the jug is placed in a warm situation under a 'cosey,' in order to keep up the heat. At the end of an hour, or an hour and a half, the product is boiled for two or three minutes. It can then be used like ordinary milk.

The object of diluting the milk is to prevent the curdling which would otherwise occur, and greatly delay the peptonising process. The addition of bicarbonate of sodium prevents coagulation during the final boiling, and also hastens the process. The purpose of the final boiling is to put a stop to the ferment-action when this has reached the desired degree, and thereby to prevent certain ulterior changes which would render the product less palatable. The degree to which the peptonising change has advanced is best judged of by the development of a peculiar bitter flavour, which is always associated with the artificial digestion of milk. The point aimed at is to carry the change so far that the bitter flavour is just perceived, but is not unpleasantly pronounced. As it is impossible to obtain pancreatic extract of absolutely constant strength, the directions as to the quantity to be added must be understood with a certain latitude. The extent of the peptonising action can be regulated, either by increasing or diminishing the dose of the liquor pancreatis, or by increasing or diminishing the time during which it is allowed to operate. By skimming the milk beforehand, and restoring the cream after the final boiling, the product is rendered more palatable.

Peptonised food is also conveniently prepared by means of powders (Fairchild's), each of which is sufficient to peptonise a pint of milk. It may be used for partially peptonising milk. One of the powders is mixed with a teacupful of cold water; a pint of cold milk is added and the mixture after stirring is placed for ten minutes in a vessel of water at a temperature as hot as can be borne by the hand (115°).

Peptonised Gruel.—Gruel may be prepared from any of the numerous farinaceous articles in common use—wheaten flour, oatmeal, arrowroot, sago, pearl-barley, pea- or lentil-flour. The gruel should be well boiled, and made thick and strong. It is then poured into a covered jug, and allowed to cool until it becomes lukewarm. Liquor pancrea-

tis is then added, in the proportion of a dessert-spoonful to the pint of gruel, and the jug is kept warm under a 'cosey' as before. At the end of a couple of hours the product is boiled, and strained. The action of pancreatic extract on gruel is twofold—the starch of the meal is converted into dextrin and sugar, and the albuminoid matters are peptonised. The conversion of the starch causes the gruel, however thick it may have been at starting, to become quite thin and watery. The bitter flavour does not appear to be developed in the pancreatic digestion of vegetable proteids, and peptonised gruels are quite devoid of any unpleasant taste. It is difficult to say to what extent the proteids of the meal are peptonised in this process. The product gives an abundant reaction of peptone; but there is a considerable residuum of undissolved material. Most of this, no doubt, consists of insoluble ligneous tissue, but it also contains some unliberated starchy and albuminous matter. Peptonised gruel is not generally, by itself, an acceptable food for invalids, but in conjunction with peptonised milk (peptonised milk-gruel), or as a basis for peptonised soups, jellies, and blanc-manges, it is likely to prove valuable. It is perhaps best reserved for rectal feeding.

Peptonised Milk-gruel.—This is the preparation of which the writer (W. R.) has had the most experience in the treatment of the sick, and with which he has obtained the most satisfactory results. It may be regarded as an artificially digested bread-and-milk, and as forming by itself a complete and highly nutritious food for weak digestions. It is very readily made, and does not require the use of the thermometer. First, a thick gruel is made from any of the farinaceous articles above mentioned. The gruel, while still boiling hot, is added to an equal quantity of cold milk. The mixture will have a temperature of about 125° F. To each pint of this mixture two or three teaspoonfuls of liquor pancreatis, and ten grains of bicarbonate of sodium, are added. It is kept warm in a covered jug under a 'cosey' for an hour or hour and a half, and then boiled for two or three minutes, and strained. If the product has too much bitter flavour, a smaller quantity of the liquor pancreatis must be used in the next operation. Invalids take this compound, as a rule, if not with relish, at least without any objection.

Peptonised Soups, Jellies and Blanc-manges.—The writer (W. R.) has sought to give variety to peptonised dishes by preparing soups, jellies, and blanc-manges containing peptonised aliment. Soups may be prepared in two ways. The first way is to add what cooks call 'stock' to an equal quantity of peptonised gruel or peptonised milk-gruel. A second and better way is to use peptonised gruel, which is quite thin and watery, instead of simple water, for the purpose of extracting the soluble matters of shins of beef and other materials employed in the preparation of soups. Jellies may be prepared by simply adding the due quantity of gelatine or isinglass to hot peptonised gruel, and flavouring the mixture according to taste. Blanc-manges may be made by treating peptonised milk in a similar way, and then adding cream. In preparing all these dishes it is absolutely necessary to complete the operation of peptonising the gruel or the milk, even to the final boiling, before adding the stiffening ingredient; for if pancreatic extract be allowed to act on the gelatine, the gelatine

itself undergoes a process of digestion, and its power of setting on cooling is thereby utterly abolished.

Peptonised Beef-tea.—A pound of finely minced lean beef is mixed with a pint of water, and ten grains of bicarbonate of sodium are added thereto. The mixture is then simmered for an hour and a half in a covered saucepan. The resulting beef-tea is decanted off into a covered jug. The undissolved beef-residue is then beaten up with a spoon into a paste, and added to the beef-tea in the covered jug. When the mixture has cooled down to about 140° F. (or when it is cool enough to be tolerated in the mouth), a table-spoonful of the liquor pancreatis is added, and the whole well stirred together. The covered jug is then kept warm under a 'cosey' for two hours, and agitated occasionally. At the end of this time, the contents of the jug are boiled briskly for two or three minutes and finally strained. The product is then ready for use. Beef-tea prepared in this way is rich in peptone. It contains about 4 per cent. of organic residue, of which more than three-fourths consist of peptone; so that its nutritive value in regard to nitrogenised materials is nearly equivalent to that of milk. When seasoned with salt it is scarcely, if at all, distinguishable in taste from ordinary beef-tea.

Peptonised Enemata.—Pancreatic extract is peculiarly adapted for administration with nutritive enemata. The enema may be prepared in the usual way with a mixture of milk and gruel, or milk, gruel, and beef-tea. A dessert-spoonful of liquor pancreatis is added to it just before administration. In the warm temperature of the bowel the pancreatic ferments find a favourable medium for their action on the nutritive ingredients with which they are mixed; and there is no acid secretion (as in the stomach) to interfere with the progress and completion of the digestive transformation. Experience has satisfied the writers that this method of administering nutriment is a valuable resource when the stomach is obstinately intolerant of food, or when there is obstruction in the higher portions of the digestive tract.

Peptonised beef is made by digesting beef with artificial gastric juice. It is very bitter, and is best administered in suppositories, each of which contains 30 grains of the preparation.

Uses of Peptonised Food.—The employment of food which has been wholly or partially peptonised is indicated when the natural digestive powers are from any cause enfeebled or suspended. The most striking benefits have been observed in cases of gastric catarrh with pain and intolerance of food; in gastric ulcer; in the anorexia and dyspepsia associated with valvular heart-disease; and in the various forms of pyloric and intestinal obstruction. Good results have also been obtained in cases of defective nutrition and intestinal irritation in infants, and in infective diseases with intolerance of food. In using peptonised food it is well to remember that it does not keep well, especially in warm weather. Accordingly it should either be prepared twice a day so that it may be never more than twelve hours old; or, if a quantity sufficient for the twenty-four be prepared at once, the portion which remains over at the end of twelve hours should be re-boiled.

WILLIAM ROBERTS.
SIDNEY MARTIN.

PERICARDIUM, DISEASES OF THE

PEPTONURIA.—A condition in which the urine contains peptones. See ALBUMOSURIA.

PERCUSSION (*percutio*, I strike).—A method of physical examination, performed by striking gently some part of the body, especially the chest or abdomen, for the purpose of producing certain sounds or tactile sensations. It may be performed either by the finger or fingers of one hand striking the surface directly; or indirectly, the fingers of the other hand being interposed; or by means of a special instrument or instruments. See PHYSICAL EXAMINATION.

PERIARTERITIS.—See ARTERIES, Diseases of.

PERICÆCAL ABSCESS.—See APPENDIX VERMIFORMIS, Inflammation of.

PERICARDIUM, Diseases of the.—SYNON.: Fr. *Maladies du Péricarde*; Ger. *Krankheiten des Herzheutels*.

Diseases of the pericardium will be considered in the following order: (1) Congenital defects; (2) Hæmopericardium; (3) Hydropericardium; (4) Melanosis; (5) Milk-spots; (6) Acute Pericarditis; (7) Chronic Pericarditis; (8) Pyopericardium; (9) Pyo-pneumopericardium; (10) Tuberculosis; (11) Tumours.

1. **Congenital defects.**—The parietal layer of the pericardium may be almost entirely absent, being represented only by a fringe of membranous projections around the roots of the great vessels; the epicardium is then in contact with the pleura. The condition is very rare and does not appear to be of clinical importance.

2. **Hæmopericardium** (*Effusion of blood within the pericardial sac*) may occur from rupture of an aneurysm of the ascending arch of the aorta; from wounds or rupture of the heart, the aorta, or a coronary vessel; or from the unexplained hæmorrhage connected with hæmophilia, purpura, and profound conditions of anæmia. Rarely an aneurysm of the descending aorta may rupture into the pericardium from without. The effusion in acute pericarditis is occasionally hæmorrhagic, but this is not usually classed as hæmopericardium. The condition leading to the hæmorrhage is usually fatal, death resulting directly from embarrassment of the heart's action by the effused blood (see HEART, Wounds of; THORACIC ANEURYSM). At the autopsy the pericardium is found much distended, and may appear of a dark bluish colour before it is opened. The blood within the sac is usually partially clotted: the amount effused is the measure of the force of the arterial pressure acting against the resistance offered by the pericardium. In cases due to rupture of the aorta or of an aneurysm, sudden fatal syncope occurs. When life is prolonged for a few hours, the dyspnoea and pallor are suggestive of severe hæmorrhage. The physical signs of the condition would resemble those of a large serous effusion (see below), but death is usually too rapid to allow a diagnosis to be made during life. Treatment is only possible in traumatic cases (see HEART, Wounds of).

Petechiæ, or small extravasations of blood beneath the serous membrane, are frequently found in infective diseases and in chronic wasting conditions.

3. **Hydropericardium** (*Dropsy of the Pericardium*).—These terms are applied to an effusion

of serous fluid into the pericardial sac, which is not due to inflammation. It may occur in cases of general dropsy, cardiac or renal; and is also said to result in rare instances from obstruction to the coronary or pericardial veins, as in cases of thrombosis of the coronary vessels or sinus, of mediastinitis, or of mediastinal tumour. In severe anæmia a large quantity of fluid is occasionally found in the pericardium at the autopsy; indeed it is the rule in such cases to meet with some increase beyond the amount normally present. It is probable that many cases of large effusions classed as hydropericardium are in reality inflammatory in nature; for it appears physically impossible that a merely dropsical effusion can exert a pressure sufficient to stretch the pericardial sac to any great extent. The physical signs presented in cases of dropsy of the pericardium resemble those of inflammatory effusion, but no friction-sound is produced. The heart may be impeded in its action by the surrounding fluid, and the symptoms of failure may ensue or be aggravated if already existing. The condition is, however, not a common one: it does not occur in general dropsy until after the appearance of ascites and hydrothorax; and relief should be sought rather by treatment of the general disease and by draining the other cavities than by any interference with the pericardial effusion.

4. **Melanosis** (*Black pigmentation of the parietal pericardium*) is a condition occasionally met with. Its exact causation is unknown. It is associated with the presence in the pericardial fluid of cells containing particles of pigment.

5. **Milk-Spots** (*maculæ albidæ*) are opaque patches found on the epicardium—occasionally also upon the parietal pericardium—in the hearts of adults and rarely of children. The most common situation is upon the anterior surface of the right ventricle; but these spots may also occur on the left ventricle near the apex and elsewhere. They are generally single, but may be multiple. It is probable that milk-spots are of the nature of callosities, produced by contact between the heart and the chest-wall. They are of no clinical significance; but it is possible that in rare instances they may give rise to friction-sounds and thus lead to a mistaken diagnosis of pericarditis.

6. **Acute Pericarditis** (*Acute Inflammation of the Pericardium*).

ETIOLOGY.—By far the commonest cause of acute pericarditis is (1) rheumatic fever. Thus of 74 cases of pericarditis recently in the wards of Charing Cross Hospital 53 were of a rheumatic nature, while among 350 patients suffering from acute rheumatism pericarditis occurred in 28 (8 per cent.). The second most important cause of this affection is (2) acute and chronic nephritis. Both the tubal and the interstitial form of renal disease are associated with pericarditis, but it is commonly seen in cases of granular kidney, occurring late in the disease, often as a precursor of uræmic symptoms and a harbinger of approaching death. (3) Extension of inflammation from neighbouring structures may involve the pericardium under many conditions. The most common of such causes is probably acute lobar pneumonia: others are myocarditis—the result of septic infection of the heart-wall—empyema, abdominal suppuration, and mediastinitis. Abscesses of the mediastinum, or of parts beneath the diaphragm, may burst directly into the pericardium in rare instances. (4) Traumatic infection

of the pericardial sac may be brought about by penetrating wounds and by fractured ribs, while a non-infective pericarditis may perhaps result from blows, or crushing of the chest-wall. (5) Infective organisms may be carried by the blood to the pericardium, as in septicæmia and pyæmia. (6) Certain general diseases, such as the acute specific fevers (especially scarlatina, variola, enteric fever and erysipelas), may be associated with inflammation of the pericardium: this also occurs in diabetes mellitus and in certain blood-diseases, such as scurvy and purpura. (7) Tuberculosis may attack the pericardium, as it does other serous membranes, and (8) tumours, both carcinoma and sarcoma, affecting the serous membrane may be associated with irritation and effusion around the actual growths.

Age and Sex.—Males are more liable to pericarditis than females. Rheumatic pericarditis attacks especially children and young persons, being comparatively rare in those over 25 years of age. Pericarditis associated with renal disease is commoner in elderly persons.

BACTERIOLOGY.—The organisms most frequently found in connection with this form of inflammation are streptococci, staphylococci, the pneumococcus and the *Bacillus tuberculosis*. It is possible that the streptococcus often recorded as present in rheumatic cases may have been in reality the organism recently described by Poynton and Paine as the specific cause of rheumatism. The pneumococcus is found in cases associated with lobar pneumonia: it may also be found in pericarditis occurring primarily and alone, while the involvement along with the pericardium of some other or of all the serous membranes is not very uncommon, and may be due to the same organism. In cases of wasting disease pericarditis is probably due to invasion by pyogenic organisms, the resistance of the tissues being lowered: this may also occur in tubercular cases, in which streptococci may be found in the pericardial exudation along with a few tubercle-bacilli; the latter apparently only accidentally present. Whether the pericarditis of renal disease is due to organisms thus enabled to establish a footing, or to toxins elaborated within the body (auto-intoxication), is not certain. In three cases reported recently by Chatin the toxicity of the blood-serum was constantly below normal and the pericardial effusion sterile. In cases associated with abdominal suppuration the *Bacillus coli communis* is probably responsible for the inflammation, and in cases associated with gonorrhœa the *Gonococcus*.

PATHOLOGY AND MORBID ANATOMY.—In the pericardium, as in other serous membranes, the inflammatory process may assume various forms, which are generally classed as (1) dry or plastic inflammation; (2) sero-fibrinous effusion; and (3) purulent effusion (*pyopericardium*). In some cases the effused fluid may be hæmorrhagic. The difference in the character of the process is due to varying virulence in the organisms or toxins which produce the condition. The earliest phenomenon in all cases is probably hyperæmia of the serous membrane, produced by dilatation of minute blood-vessels; this is quickly followed by exudation of a smaller or larger quantity of fluid on to the surface. The endothelial cells become swollen and granular, and some of them are cast off. To the naked eye the surface of the pericardium appears dull and opaque, losing its characteristic polish. The opposed surfaces, visceral and parietal, suffer together, but the

inflammation may either be limited to a small area of the sac or may involve the whole of its extent. On looking at the pericardium *post mortem* increased vascularity may be apparent before the sac is opened, a network of small vessels being visible all over the exposed surface between the anterior margins of the lungs; the latter are frequently adherent to the pericardium owing to outward extension of the inflammation. On cutting through the epicardium into the heart-muscle a zone of redness may be seen of appreciable thickness beneath the serous membrane, suggesting involvement of the myocardium; but though this does frequently occur it may often be found that the thin layer of fat lying beneath the epicardium is alone inflamed, thus acting as a protection to the important muscle beneath it. Microscopically, the pericardium is found thickened and infiltrated with round cells, which are probably in part emigrated leucocytes, and in part the offspring of the connective tissue-cells. The endothelial cells disappear at an early period of the disease. The phenomena thus far described are common to all forms of pericarditis. If the process goes no further, the *dry* or *plastic* variety results. The opposing surfaces are roughened and studded with small fibrinous excrescences, or covered with a thin layer of the same material. If the patient survive, more or less organisation of the new material occurs, and adhesion takes place between the two surfaces, or connecting threads or bands of fibrous tissue are produced by the continual movement of the heart. These may rupture and remain adherent only by one extremity. The filaments thus resulting may be so numerous and so closely set together as to give the heart the appearance of being covered with a shaggy coat of hair (*cor hirsutum*). When complete adhesion takes place the condition of chronic pericarditis or adherent pericardium is produced (see p. 1186). In other cases the amount of fluid which escapes from the dilated blood-vessels is much greater, and *serous* or *sero-fibrinous effusion* is the result. The amount varies from one or two ounces up to a pint or more. In the latter case the pericardial sac is distended and takes the form of a gigantic pear, the larger part being downwards; in cases of very large effusion the shape becomes almost globular. The fluid is either clear, yellow, transparent serum, or may be turbid from flocculi of coagulated fibrin, or, in rare cases, hæmorrhagic. It contains a large amount of albumen along with fibrinogen and fibrin-ferment, so that it may coagulate spontaneously. In cases due to the pneumococcus, this organism may be present in enormous numbers in the fluid; in other cases, other varieties of bacteria may be demonstrated by staining. The pericardial lining is generally coated with velvety lymph. In many cases the amount of fluid which exudes is much less, and there is practically a combination of the 'dry' with the 'wet' variety of pericarditis: the two layers of pericardium are adherent throughout a large part of their surfaces by means of thick fibrinous coagulum, while in the pockets remaining there are found collections of fluid, more or less turbid and opaque. In rare cases due to septic infection the effusion is purulent in character (see p. 1187—*Pyopericardium*). If the inflammatory process subsides, the sero-fibrinous fluid is gradually absorbed, but the damage done to the endothelium cannot be repaired. The condition remaining is similar to that found in the simple plastic variety. Adhesion takes place between the

opposed surfaces, and the cavity of the pericardium is more or less completely obliterated.

RESULTS.—The results arising from simple plastic pericarditis are not in themselves considerable, apart from injury to the cardiac muscle, which may accompany the pericarditis, and from the effects of subsequent adhesion (see p. 1186). Some authorities, however, consider that the pericardium normally acts as a support to the heart: according to this view the weakening of the membrane produced by inflammation may be a factor in the causation of the dilatation and failure of the heart which frequently occur. In cases in which there is much effusion the fluid surrounding the heart presses upon it and impedes its action. The enlargement of the sac may also cause pressure upon the œsophagus and resulting dysphagia. Pressure upon the lungs may produce collapse of portions of these organs, especially of the left lung. It has been suggested that the pleural effusion often found along with pericardial may be due in some cases to pressure exerted upon the veins in the mediastinum. The effect of the effusion upon the position of the heart itself has been much discussed. In all probability no constant alteration in position takes place, but the clinical fact of the appearance of the cardiac impulse in a higher situation than usual has not been satisfactorily explained.

CLINICAL FEATURES.—The onset of pericarditis is in the majority of cases insidious. In acute rheumatism it generally appears, if at all, within the first week or ten days of the illness, and more often in earlier than later attacks. The patient may not complain of any additional distress at first, or he may be conscious of a feeling of weight or tightness in the chest. With the exception of the *alae nasi*, which move with respiration, his face is often fixed and his expression anxious. In some cases there is pain in the præcordial region, which may be well marked or even violent; it may be of an aching, burning, or stabbing character, and may be referred to the epigastrium rather than the chest. The respiration is generally quickened, and the pulse full, soft, and increased in frequency. The heart's action may be tumultuous, and palpitation be complained of. The patient's temperature may rise with the onset of pericardial inflammation (101° F. to 103° F.), but in a large number of cases there is no fever. The occurrence of an initial rigor is quite exceptional, and is suggestive of suppurative pericarditis. There may be a short dry cough. In this early stage the physical examination of the patient can alone be relied upon to discover the condition. Tenderness is often found in the præcordial area upon pressure or percussion; in some cases this hyperæsthesia is very pronounced. The hand laid upon the chest may occasionally perceive a sensation as of two rough bodies rubbed together—thrill or friction-fremitus. Auscultation reveals a peculiar characteristic sound or sounds occurring along with, rather than replacing, the normal cardiac sounds. At first it is usually soft and 'whiffing' in character, but it may be harsh and creaking or almost grating. It may occur with both systole and diastole, or may not exactly correspond with either period of the cardiac cycle. A very typical auscultatory phenomenon is the 'triple rhythm' produced by co-existence of the two normal cardiac sounds along with a single adventitious friction-sound; at other times four distinct sounds are heard with each cycle of the heart,

a rhythm which has been compared to the distant puffing of a train leaving a station. Friction-sounds are confined to the præcordial area, and are usually loudest at the base of the heart. Their intensity may be increased by pressure of the stethoscope upon the chest-wall. They have a peculiar superficial quality, as if produced near to the surface of the thorax; and they may alter in intensity with the respiratory rhythm.

In severe cases delirium frequently occurs. It is generally of the noisy, active variety, but may be low and muttering. It is often combined with sleeplessness. The latter may be a troublesome symptom, even when the mind remains clear, as it occasionally does throughout, even in fatal cases. Hiccough is sometimes present, and vomiting may be a distressing and serious feature. The patient generally lies on his back, but may toss about restlessly from side to side. The face is often dusky and the expression anxious.

If the myocardium is seriously involved, symptoms of failure of the heart may appear—a running pulse, urgent dyspnoea, and cyanosis. Death may occur either suddenly by syncope or gradually by exhaustion. When recovery takes place the symptoms gradually diminish in intensity, but relapse may occur in some instances.

When effusion occurs the pain usually disappears; but if the amount of fluid be large the other symptoms may be accentuated. Dyspnoea is generally a prominent feature, and the patient may need to be propped up in bed or even to assume a bent posture with the head held down towards the knees. In extreme cases the cyanosis is marked, the *alæ nasi* work vigorously, and the distress of the sufferer is suggestive of grave disturbance. Physical examination will reveal an increased area of cardiac dullness. This increase is generally first noticed in the upper and left portion of the pericardial area—the dullness extending upwards to the second interspace or even higher—owing to the looseness of the pericardium at the roots of the great vessels, whereby it readily allows the accumulation of additional fluid in this region. As the effusion increases the lower portion of the pericardial sac also stretches and the dullness extends to the right of the sternum and beyond the apex of the heart, so that the whole area is triangular in shape, the base being on the diaphragm. The cardiac impulse may be diffused and present a peculiar wavy character; the apex-beat is often raised, being for a time recognisable in the fourth interspace. In children the wall of the chest may bulge forwards in the præcordial region. In cases of very large effusion an area of diminished resonance on percussion may be found behind at the angle of the left scapula, and also at the bases of the lungs near to the spine. The friction-sound audible at the beginning of the attack frequently disappears when effusion takes place; in other cases, however, it persists at the base of the heart throughout the illness. The normal cardiac sounds have a distant or muffled character; the action of the heart may be irregular, and an alteration of the pulse with the respiratory rhythm has been occasionally observed. The patient may complain of pain of a burning or stabbing character in swallowing, due to pressure of the bolus of food upon the inflamed and tender pericardium; actual difficulty in swallowing may occur, owing to pressure of the distended sac upon the œsophagus.

When the inflammatory process subsides absorption of the effused fluid rapidly takes place. The friction-sound generally returns at this stage, and the character of this sound may be rougher than at first; friction-fremitus is also more likely to occur. If a fatal result be impending the symptoms of cardiac failure are similar to those previously described as found in the 'dry' form of the disease.

The account first given of rheumatic pericarditis applies in the main also to cases which are secondary to pneumonia or pleurisy. In patients suffering from renal disease the onset of pericarditis is still more insidious, and the condition is frequently overlooked. Restlessness may be a marked feature, no pain being complained of, and delirium, drowsiness, or other uræmic symptoms may rapidly ensue. In other cases breathlessness is seen with rapid, feeble pulse, and much distress and anxiety, or even actual pain: this may be referred to the abdomen rather than to the chest. The frequency of the pulse and respiration are usually much increased, and the aspect may suggest the onset of some grave complication, the face seeming pinched, the eyes hollow, and the expression careworn. The temperature may be raised, but here, too, there is frequently no pyrexia to suggest the existence of an inflammatory process.

DIAGNOSIS.—In a few cases pericarditis may be present without giving rise to any distinct signs by which it can be recognised; much more often it is missed through not being looked for. In all cases of rheumatism, in acute pneumonia and other infective conditions, and in renal disease, it is most important to bear in mind the possibility of the occurrence of this complication, and to examine the heart frequently and methodically. In children, even apart from symptoms of rheumatism in the joints, the occurrence of fever and some degree of dyspnoea with a pulse which is more rapid than the general symptoms warrant, should give rise to a suspicion at least of the existence of pericarditis; even infants are not free from liability to the disease, and young adults may suffer from it without very well-marked joint-symptoms. The occurrence of delirium in the course of rheumatic fever should always suggest the onset of pericarditis. The dry form of the disease can only be certainly recognised by means of the characteristic friction-sound. It is possible that certain sounds produced by contact of the heart with the pleura, or by its rhythmical pressure upon a portion of the lung, may simulate this. As a rule, however, these cardio-pulmonary sounds alter much more with the respiratory rhythm than does the *bruit* in true pericarditis; the symptoms of serious disease are also absent in these cases. Endocardial murmurs may in rare cases give rise to doubt, but these are generally distinguished by their typical localisation, their conduction beyond the confines of the pericardium, and the absence of the peculiar superficial quality observed in most pericardial sounds.

Pericardial effusion of a dropsical nature may be indistinguishable from that arising from inflammation: the presence of a friction-sound would establish the existence of the latter, while hydro-pericardium never occurs to any serious extent until ascites and hydrothorax are already present.

A more difficult problem in diagnosis is presented by cases of dilatation of the heart, such as occurs owing to adherent pericardium or in the late stages of mitral disease. Here there may be increase of

præcordial dullness extending over an area of the chest practically identical in shape with that affected in cases of pericardial effusion; the cardiac impulse may be diffuse and wavy, the pulse frequent and soft, and cyanosis and dyspnoea be present owing to the failing action of the heart. In the absence of a friction-sound, or of a knowledge of the earlier physical signs, diagnosis may be impossible; and owing to the existence of such cases the operation of exploring the pericardium with a hollow needle is to be deprecated. Theoretically a localised empyema in the cardiac region might give rise to difficulties in diagnosis; the two conditions may co-exist and the pleural condition be overlooked owing to the predominance of the pericardial phenomena. Hæmorrhage into the pericardium is generally accompanied by almost immediate syncope and is rapidly fatal.

PROGNOSIS.—The immediate outlook varies greatly with the cause of the inflammation. In rheumatic cases recovery is the rule: thus out of 53 cases of this affection occurring in Charing Cross Hospital 10 died (under 20 per cent.). The mortality of this disease is heavy among young children and infants. The occurrence of great dyspnoea with cyanosis and a running or irregular pulse is of grave import: vomiting and the appearance of a low muttering form of delirium are also of bad omen. Cases of pericarditis associated with pneumonia are very prone to terminate fatally: out of 13 cases of this complication 8 succumbed (over 60 per cent.). In cases of renal disease the onset of pericarditis is almost invariably a fatal sign. Occasionally 'rheumatic' pericarditis may complicate Bright's disease; such cases are less frequently fatal.

In patients who recover from the acute attack some degree of adhesion between the layers of pericardium is left. This tends, especially in young persons, to embarrass the action of the heart and to increase the difficulty of establishing due compensation for any co-existing valvular defects. Thus there can be little doubt that in such cases the occurrence of pericarditis tends to shorten life and to render the appearance of heart-failure probable in later adult life (*see below*, Chronic Pericarditis). For purposes of life-assurance the occurrence of an attack of pericarditis would justify the addition of five to ten years to the applicant's actual age.

TREATMENT.—When pericarditis occurs in the course of acute rheumatism little additional treatment is as a rule necessary beyond that adopted for the primary disease. Complete rest is essential, the patient being carefully warned against any sudden exertion, such as sitting up or attempting to get out of bed. Any attitude which is most comfortable may be adopted, a semi-recumbent position maintained by means of pillows being often more restful than a horizontal posture. Milk-diet is to be continued: salicylate of sodium may also be given—indeed the depressing action of the drug upon the heart, when not too pronounced, is actually an advantage, for the excited action of the organ needs to be controlled in order that relative rest may be obtained. Pain may be soothed by means of either hot or cold applications to the præcordia: thus some patients find an ice-bag soothing and quieting, while others resent the application of cold and welcome that of hot fomentations. Blistering of the cardiac area is practised

by some authorities; it has the inconvenience of rendering subsequent auscultation difficult, and is of very doubtful efficacy. More relief may be obtained from the application of leeches: six, ten, or twelve of these may be used according to the age of the patient and the general condition; they should be applied along the left border of the sternum and over rib-cartilages rather than in the intercostal spaces, in order that any excess of hæmorrhage subsequently resulting may be more easily controlled by pressure. If the pain is not relieved by these means, opium or morphine (hypodermically) may be given with care in the early stage of the affection, when there are no signs of failure of the heart. Should such failure occur, stimulants are needed. Alcohol may be given in amounts rising from two to twelve ounces or even more. Ether, ammonia, strychnine and digitalis may all be employed; and inhalations of oxygen appear useful in some cases. If sleeplessness is a prominent and distressing symptom chloralamide is perhaps the safest hypnotic to use; chloral hydrate may also be given with care along with a little aromatic spirit of ammonia to counteract the depressing effect. Morphine may be necessary if insomnia persist, and may be given hypodermically along with small doses of strychnine. In cases in which effusion has occurred the above measures may still be tried. If the effusion be very large the question of its removal may arise. In view of the difficulty, previously alluded to, of distinguishing dilatation of the heart from pericardial effusion, and of the uncertainty that must exist as to the exact position of the heart, it is advisable to adopt the open method of incision (*see PERICARDIUM, Surgery of*) rather than to insert an aspirating-needle. If pleural effusion co-exist with pericardial, the former effusion should be previously removed, since the relief thus obtained to the lymphatics of the thorax may result in rapid absorption of the pericardial fluid. Owing to the danger of relapse the patient should be kept in bed for at least ten days after the symptoms have subsided; salicylates should be reduced very gradually and solid food as gradually permitted. It is possible that a certain degree of absorption of fibrinous or embryonic adhesions may be brought about by the administration of iodide of potassium; 5-grain doses of this drug three times a day might therefore be administered during this period; such absorption may perhaps be aided by light blistering of the præcordial area or counter-irritation with Liquor Iodi Fortis. Iron and quinine may be useful in the convalescent stage, and the greatest possible care must be subsequently taken to guard against exposure to chill, damp, or other condition that may favour recurrence of rheumatism (*see RHEUMATISM*).

7. Chronic Pericarditis (Adherent Pericardium).—This condition is the result of previous acute attacks. It consists in the adherence described above between the visceral and parietal layers of pericardium. The adhesions are formed by the 'organisation' of the effused lymph, that is to say, by the growth of connective tissue-cells into the coagulum, and the union of the opposed surfaces by this means. New blood-vessels form in the fibrous tissue, and this tends to shrink as it grows older, and thus to hamper the action of the heart. Extension of the inflammation to or from neighbouring parts may result in adhesion of the

pericardium externally to the chest-wall, the pleuræ, and the structures within the mediastinum. In some cases, especially those associated with mediastinitis, the fibrous coat surrounding the heart and binding it to surrounding structures is very thick; it may be almost cartilaginous and occasionally becomes infiltrated with calcareous salts—a condition which has given rise to the description of a ‘bony heart.’ When the heart is thus surrounded by a fibrous coat two possible results may occur. If the constricting tissue be very dense, the heart is unable to enlarge and is at the same time forced to work at great disadvantage owing to the resistance offered to systole by the adhesions. In such cases fatal failure of the heart necessarily ensues rapidly. In other cases the fibrous tissue may stretch and allow the heart to enlarge, which it does to a very great extent in response to the continual impediment offered to its action. This condition is frequently seen in rheumatic pericarditis. Failure of the heart in such patients is much less rapid but is none the less certain to occur ultimately. Various clinical signs have been described as indicating the existence of adherent pericardium. Of these the more important are retraction of the chest-wall—especially of the lateral wall of the thorax (Broadbent’s sign)—along with the cardiac systole, diffusion of the cardiac impulse, fixity of the position of the apex-beat in spite of change of posture, persistent enlargement of the area of cardiac dullness and disappearance of the pulse with inspiration (‘pulsus paradoxus’). It is evident that the mere existence of adhesion between the two layers of the pericardium cannot by itself give rise to any of these phenomena, all of which are dependent upon fixation of the heart and pericardium not only to one another but to external parts. Even in the last-mentioned condition no one of these signs is constantly present, and it must be confessed that certain diagnosis of the condition is impossible. In cases of mediastino-pericarditis (mediastinitis) great enlargement of the liver is usually the most prominent feature, pleural effusion is generally present, and general dropsy and anasarca occur (see MEDIASTINUM, Diseases of). Apart from this condition, pericardial adhesion may be suspected in cases of rheumatism presenting chronic cardiac enlargement without signs of valvular disease, or of rheumatic endocarditis in which the enlargement of the heart in all directions is greater than the amount of valvular lesion will account for. In children who have suffered from successive attacks of rheumatism, the pericardium is very frequently found universally adherent at the *post-mortem* examination. Failure of the heart to respond to the usual remedies is frequently due in such cases to the existence of this condition. No therapeutic measures will avail to absorb connective tissue that has once become fibrous. Treatment can only be directed to placing the patient under the most favourable general conditions, avoiding all strain upon the heart and all causes which aggravate existing disease of the valves, and meeting symptoms of cardiac failure, when they arise, by the usual measures. In very rare cases a chronic pericardial effusion may exist and may re-accumulate after tapping.

8. Pyopericardium (*Suppurative Pericarditis*).—The pathology of this condition has already been alluded to (see p. 1183). It may occur as a result of penetrating wounds, by which pyogenic organisms are carried into the pericardium;

from rupture of abscesses or vomicæ from without into the sac, or extension of the lesions of ulcerative endocarditis through the myocardium; and from general septic processes such as pyæmia and septicæmia. It may also be the final stage of a sero-fibrinous pericarditis, just as empyema may succeed to a serous effusion. In rare cases the pus is putrid and stinking, especially if air has gained entrance to the cavity. There are no means of certainly distinguishing purulent effusion from the serous variety, except exploration of the pericardium; although the occurrence of rigors and of hectic temperature establish a strong probability in favour of the former. Exploration should be done if the condition of the patient be grave and the cause of the effusion be such as to render the existence of suppuration probable. See PERICARDIUM, Surgery of.

9. Pyo-pneumopericardium (*Gas in the Pericardium*).—This is a very rare condition, and may be produced by penetrating wounds, by ulceration of carcinoma of the œsophagus into the pericardium, or by rupture into it of a tubercular cavity or of a subphrenic abscess communicating with the stomach or intestine. The presence of gas in the pericardium is almost invariably associated with suppurative, and the pus is frequently putrid and offensive. If the patient be already in an exhausted state there may be no sign to indicate the occurrence of the condition: usually there will be sudden anxiety, dyspnoea, and collapse. The præcordial region appears full; the impulse is feeble or absent; and the churning of gas and fluid produced by the movements of the heart may convey a peculiar sensation to the hand, and be audible as a splashing or rattling noise. A tympanitic percussion-note may be present over the præcordia. Succussion-splash and the bell-sound are said to have been obtained in some cases. The only other condition which may possibly give rise to similar phenomena and lead to an error of diagnosis is the existence of a large pulmonary cavity in the cardiac region near the surface in such a position that the movements of the heart produce splashing of its contents. Prognosis is probably hopeless. The only possible treatment is by incision and drainage of the sac.

10. Tuberculosis of the Pericardium.—In cases of general tuberculosis, miliary tubercles may occur beneath the endothelium of the pericardial sac, but the condition is very uncommon. Chronic tubercular nodules may occur on its walls and give rise to bands of adhesion. These are always secondary to tubercular disease in other organs, especially the lungs. Pericarditis occurring in tuberculous subjects is not always associated with the presence of tubercle-bacilli or with microscopical appearances characteristic of this disease; in such cases it is probably due to infection by other bacteria.

11. Tumours of the Pericardium.—Secondary nodules of carcinoma and sarcoma may occur in the walls of this cavity; they are generally associated with a certain amount of effusion, which is frequently hæmorrhagic. The pericardium may become infiltrated by new-growths arising in the mediastinum. See also p. 1139.

H. MONTAGUE MURRAY.
W. CECIL BOSANQUET.

PERICARDIUM, Surgery of.—Paracentesis of the pericardium for the relief of distension of that cavity must be looked upon chiefly as a palliative

measure, by giving the heart a temporary freedom from the embarrassing fluid surrounding it. At the outset one may state that a distended pericardium cannot be reached with absolute certainty by the exploring needle. Owing to the dislocating effects of old adhesions or of pressure the needle may not enter the pericardium at all, but penetrate the lung, pleural cavity, or even the heart, especially if that organ has become adherent to the pericardium. It is important to remember that the diagnosis between hydropericardium and certain forms of dilated heart may be very difficult (see p. 633 and p. 1185). The writer has known of two cases in which a dilated heart has been punctured on the supposition that there was fluid in the pericardium, and in each case the autopsy revealed a pure hæmopericardium caused by the exploring needle.

At the base of the pericardium, on its anterior aspect, there is a small recess from $\frac{1}{2}$ to $\frac{3}{4}$ inch in depth. In the normal condition this is of course collapsed, but when fluid collects in the pericardium it becomes distended, and then lies opposite the sixth intercostal space on the left side, just at the edge of the sternum. At this spot the pleuræ have diverged from the middle line, and this recess can therefore be reached without opening the left pleural cavity. Unfortunately for practical purposes this little recess of the pericardium is difficult of access owing to the narrowness, or even obliteration, of the sixth intercostal space at this spot by the approximation or junction of the sixth and seventh ribs. Many writers have accordingly recommended a spot above this level on the left side. Here, however, the pleural cavity is very likely to be transfixed, and if pus is present in the pericardium there is considerable probability of the pleura becoming infected.

The operative procedures upon the pericardium are :—

A. Aspiration of the Pericardium (*Paracentesis Pericardii*).—If this operation is performed for diagnostic purposes only, the needle should be a very fine one, such as that of Pravaz. A small vertical incision, $\frac{1}{2}$ inch long, is made at the left border of the sternum at the level of the fifth intercostal space. The needle is then directed backwards exactly at the left border of the sternum so as to avoid the internal mammary artery, which generally lies a little way from the border of the sternum. If fluid is found, the exploring syringe may be withdrawn, and a larger needle attached to an aspirator inserted with a view to removing the fluid. During this procedure the patient should be propped up in bed with pillows, and every available method of stimulating the heart should be ready for immediate use in the event of sudden failure of its action. Apart from the relief afforded by the removal of a mechanical obstruction to cardiac action, the fluid in some cases does not re-form, and so permanent benefit may result.

B. Drainage of Pericardium (*Pericardiotomy*).—A small semicircular flap of skin is made with its base at the left edge of the sternum, extending vertically from the fourth to the sixth space inclusive, and measuring about 5 inches in radius. The fourth, fifth, and sixth costal cartilages are then removed along the whole extent explored; the intercostal muscles and aponeuroses are carefully cut at the edge of the sternum and turned outwards as a flap so that the internal mammary artery is exposed. This vessel is double-ligatured, divided, and drawn

aside with fibres of the triangularis sterni muscle and the reflected fold of the left pleura. The distended pericardium is then carefully incised; the contents evacuated; and a small soft drainage-tube inserted: this should lie at the lowest part of the cavity. The incision into the pericardium should then be sewn up except at the point where the drainage-tube projects.

HENRY PERCY DEAN.

PERIHEPATITIS (*περί*, around; and *ἥπαρ*, the liver).—Inflammation of the capsule of the liver. See LIVER, Inflammation of.

PERINEPHRITIS (*περί*, around; *νεφρός*, the kidney).—SYNON.: Fr. *Périnephrite*; Ger. *Perinephritis*.

DEFINITION.—An acute or chronic inflammation of the fibro-fatty envelope of the kidney, terminating occasionally in resolution, but more frequently in suppuration and the establishment of a chronic purulent discharge.

ÆTIOLOGY.—Perinephritis may develop as a primary affection after exposure to cold, or in association with wounds, bruises, and strains. It may follow surgical operations on the lower urinary passages, testicle, or spermatic cord; and it may also arise in the course of, or as a sequel to, the acute specific fevers, pyæmia and puerperal fever. The disease, however, originates most frequently in a secondary manner in connection with suppurative nephritis or pyelitis, either by direct perforation or by infection through the local veins and lymphatics. It is specially related to calculous pyelo-nephritis. It may also arise by extension from lesions of more distant parts in the abdomen or pelvis, including the cæcum, colon, appendix vermiformis, uterus, gall-bladder, spleen, and spinal column; or in association with thoracic inflammations, such as pneumonia, abscess of the lung and empyema. Perinephritis may occur at any age, but is less common in children than in adults. Among the latter, males show a slight preponderance.

ANATOMICAL CHARACTERS.—The initial congestion of the inflamed cellular tissue is followed by exudation into its meshes, which adds to its bulk and density. The subsequent changes vary in those cases that do not undergo resolution speedily, and a classification into three types has been suggested (Morris), according to the direction taken by the morbid process. *Firstly*, a hypertrophic condition of the fibro-fatty tissue may result, that may deform the kidney by compression or the growth of fibro-fatty processes into its substance; *secondly*, organisation of the exudate into firm white fibroid material, which by its sclerosis and contraction may compress the kidney and wholly obliterate its vessels; and, *thirdly*, suppuration may take place and the phlegmon become converted into a perinephritic abscess. Such abscesses may develop from a central suppuration, but often several foci of pus-formation appear, and the abscess remains for some time loculated or multiple. Hence the difficulty clinically in detecting fluctuation, and the futility in many cases of aspiration as a mode of treatment. The pus may be odourless or fetid from the decomposition of sloughs of cellular tissue floating in it. A fæcal odour may be present, even though no perforative communication with the colon exist. The abscess may attain immense size and occupy the entire loin and iliac fossa, and may ex-

tend by burrowing to the thigh or the thorax. It may be accompanied by œdema of the muscles and integuments around.

SYMPTOMS AND COURSE.—In an acute case the general symptoms are severe, the temperature rising to 101° – 105° F., with recurring rigors and a soft, rapid feeble pulse. The skin is hot and dry at the beginning, but later free perspirations occur and there is much thirst. There is marked constipation, and the urine is high-coloured and concentrated. In a few cases it may be little altered, while in others its characters may be modified by the antecedent renal or vesical disease.

The local symptoms comprise dull aching, less often lancinating, pain in the affected loin, radiating along the branches of the lumbar plexus to the thigh or knee. Slight flexion of the hip and some rigidity of the spine with inclination towards the affected side are common, evidently due to a desire to relax tension. Movement and pressure greatly aggravate the suffering. Later, a firm swelling develops which is dull on percussion. It surrounds the kidney and is inseparable from it, but it is usually possible to isolate it from the liver and spleen. It is not displaced by respiratory movements. The swelling has a solid weighty feel at first, and does not fluctuate till suppuration is well advanced. In simple perinephritis no tumefaction occurs; it is only in the phlegmonous form, that terminates in abscess-formation, that a definite mass can be felt. By its pressure on the veins, more particularly on the right side, œdema of the foot and ankle may be produced. A few cases terminate in resolution, but the majority in suppuration. The abscess so formed steadily enlarges and may discharge spontaneously by the following routes: Through the skin in the loin, groin, or thigh; through the urinary channels by bursting into the renal pelvis, ureter, or bladder; through the colon; or through the diaphragm into the pleura and lung with the establishment of a purulent expectoration. When the pus has been evacuated by any of these channels a natural cure may follow, but frequently a chronic discharging sinus remains, and the patient eventually succumbs to hectic fever or amyloid degeneration of the viscera. A rapidly fatal termination results when the abscess bursts into the peritoneal cavity, or when pyæmia or septicæmia supervene.

DIAGNOSIS.—Perinephritis is distinguished from appendicitis by observing that in the latter the pain and tenderness are anterior and iliac rather than posterior and lumbar, and by the greater disturbance of the stomach and bowels. In spinal caries with psoas abscess the onset is gradual with little or no elevation of temperature, there are bony tenderness and deformity, and the psoas abscess is less painful and has a more perfect fluctuation than the perinephric. In lumbago the pain is sharper and is referred to the muscles of the back: there is no swelling and little fever. Rupture of an aneurysm in the loin is recognised by the sudden development of the swelling, the comparative absence of fever, and by exploratory aspiration in obscure cases. In hydronephrosis there is no fever and little pain, and the fluctuation is very definite. Organic diseases of the kidney, liver, and spleen are distinguished by the situation and relations of the swelling, its consistence and the probable absence of fever. Stercoral colitis is differentiated by the doughy consistence of

the mass, and its rapid disappearance under evacuant treatment.

PROGNOSIS.—The simple form may be expected to end favourably. Phlegmonous perinephritis is a serious malady, that if unrelieved may terminate fatally in from two to four weeks. Rapid recovery in numerous cases follows operation, and in a smaller number a satisfactory result is occasionally obtained, after a tedious illness, by a spontaneous discharge through the skin, bowels, urinary passages or lung—these routes being named in the order of their relative safety. After escape of the pus, should the original cause persist, and prove incapable of removal by radical operations, death ultimately ensues from hectic fever or amyloid degeneration. If the abscess burst into the peritoneum, or pyæmia or septicæmia arise, death is inevitable in a few days.

TREATMENT.—In an acute case a hot bath, rest in bed, and saline aperients, together with the local application of hot sedative stupes and poultices, should be ordered. The advantage of local blood-letting, or even dry cupping, at the outset, is too often overlooked. The diet may consist of nutritious slops with avoidance of stimulants at this stage.

When suppuration is suspected, and even before fluctuation can be made out, a free incision under full antiseptic precautions through the fascia lumborum is indicated. With the finger introduced into the cavity septa are to be gently broken down and sloughs removed. The cavity should be thoroughly irrigated with mild antiseptic solutions and a large drainage tube inserted. This tube should not be discarded too soon owing to the great depth of the space and the tendency of the skin-wound to become valvular. Aspiration, formerly much in vogue for diagnostic and evacuant purposes, is not to be recommended, for the reason, that there may be several foci of suppuration, coagula, sloughs of tissue, calculi or other débris which cannot be satisfactorily dealt with through a needle. When a chronic sinus remains, and refuses to close after astringent injections or caustics have been applied to its walls, the possibility of a radical operation upon the kidney or other organ calculated to remove the original cause may be considered. Otherwise the patient's strength must be maintained by a liberal diet, tonics and stimulants; and the development of hectic fever or amyloid disease combated as long as possible. In those forms of perinephritis tending to sclerosis or hypertrophy of tissue counter-irritation by iodine or blisters, with the internal use of the iodides in tonic mixtures, may be employed.

THOMAS SINCLAIR.

PERINEURITIS (*περί*, around; and *νεῦρον*, a nerve).—Inflammation of the connective-tissue sheath of a nerve, usually more or less associated with neuritis. See NEURITIS.

PERIOD OF INCUBATION.—See INCUBATION.

PERIODIC PARALYSIS.—See PARALYSIS, PERIODIC.

PERIODICITY IN DISEASE.—Laycock, from a general review of the periodical phenomena observed in menstruation, in utero-gestation, in the development of the ova of fishes, and in the metamorphoses of insects, came to the conclusion that

physiological changes occur in animals at intervals of certain numbers of days or weeks. He concluded that there are critical days in health, and endeavoured to show that the changes in some diseases followed a similar rule of periodicity, reverting to the ancient doctrine of 'critical days' in fever of which Hippocrates treated. The existence of cyclical periods in fever is exceedingly doubtful, although, according to Wunderlich's observations, the majority of cases of typhoid fever run a regular course, divided into periods corresponding in time with the division into weeks and half weeks.

The two diseases in the course of which periodicity is most marked are malaria and relapsing fever. In the case of malarial fever it is now recognised that the period at which the paroxysm recurs is determined by the life-history of the parasite causing the disease. The differences between the tertian and quartan intermittents are found to depend upon differences in the parasite. In the regular intermittent fevers the parasite chiefly exists and in great part completes its cycle in the circulation; in a second group, comprising the malarial fevers which occur during the hot season of countries where malaria is most virulent, the parasite chiefly exists and in great part completes its cycle in the internal organs. In this latter group the regularity of recurrence of the paroxysms is wanting (*see* MALARIAL DISEASE). In relapsing fever also the relapses have been shown to be due to the life-history of the spirillum, the organisms increasing in number with the advent and progress of pyrexia and disappearing with its cessation. *See* RELAPSING FEVER.

Seasonal Variations.—The statistical investiga-

tions of Buchan and Mitchell have shown that most diseases have a constant relation to season, many being directly controlled by variations in temperature. Longstaffe, as the result of plotting out the death-rates from the majority of alleged causes, both compared with one another, and with curves representing meteorological elements, was led to classify diseases into four groups—hot diseases, cold diseases, dry diseases, and indifferent diseases. Among the 'hot diseases' he included diarrhoea, want of breast-milk, atrophy and debility, tabes mesenterica, thrush, enteritis and dysentery; among 'cold diseases' he included most affections of the respiratory organs, apoplexy, paralysis, mortification, heart-disease; by 'dry diseases' he meant scarlatina, puerperal fever, erysipelas, acute rheumatism and laryngitis, which he claimed are greatly checked by rainfall, especially frequent rainfall. Winter or summer maxima are thus produced, and with respect to some of these diseases the relation of the mortality to season is not difficult to understand. With others the exact conditions which determine rhythmical prevalence are not understood. The seasonal variation in mortality from some of the more common communicable maladies is well shown by the accompanying diagrams. Scarlet fever, diphtheria, and enteric fever, it will be seen, have their maxima in November, and puerperal fever, erysipelas, and rheumatism resemble them in this respect. Small-pox and whooping-cough have their maxima in the spring, and measles has two maxima. The second maximum of measles so conspicuous in the London curve is less obvious in that of some other English towns.

LONDON.

FIG. 1.—MEASLES (60 years, 1841-1900).

The mean line represents an average weekly number of 36 deaths.

FIG. 2.—SMALL-POX (60 years, 1841-1900).

The mean line represents an average weekly number of 14 deaths.

FIG. 3.—WHOOPIING COUGH (60 years, 1841-1900).

The mean line represents an average weekly number of 46 deaths.

FIG. 4.—ENTERIC FEVER (30 years, 1871-1900).

The mean line represents an average weekly number of 14 deaths.

FIG. 5.—SCARLET FEVER (40 years, 1861-1900).

The mean line represents an average weekly number of 37 deaths.

FIG. 6.—DIPHTHERIA (40 years, 1861-1900).

The mean line represents an average weekly number of 20 deaths.

Examination of the notified cases of scarlet fever and diphtheria in London has supplied evidence that these diseases manifest seasonal periodicity in other particulars than that of prevalence; thus both in respect of age-distribution of the notified cases and in respect of fatality there is seasonal variation. It is interesting to observe that the seasonal curves of prevalence do not accord with the curves of seasonal fatality, and that the months of greater prevalence, generally, have the lower fatality. Astley Gresswell, however, as the result of classifying 588 cases of scarlet fever under his care in one of the hospitals of the Metropolitan Asylums Board between September 1887 and February 1888, came to the conclusion that 'as the scarlatina mortality for the whole of London rose, most of the symptoms increased in relative frequency and severity; and that as the prevalence and mortality subsided, so also did the relative frequency and severity of most of the symptoms.' It may be that explanation of the difference between the conclusions suggested by Gresswell's observations and the London notification-figures is due to the fact that hospital cases represent selected cases, the more severe cases being sent to hospital. In the absence of notification of whooping-cough and measles in London, there is no opportunity of determining whether these diseases are subject to similar seasonal variations in fatality, but there is marked seasonal variation in the age-distribution of the deaths, those under one year of age occurring in much greater proportion in the months of May, June, July, August, and September, than in other months of the year, and the maximum occurring in whooping-cough in August and in measles in July.

Variations in periods of years.—Longstaffe (*Studies in Statistics*) has brought out some new and important points in regard to the broader cycles which extend over periods of years. He found that from 1855 to 1880, not only in London, but also in England generally, scarlet-fever mortality rose and fell with considerable regularity at intervals of five or six years, the actual maximum having occurred in 1858, 1863-64, 1869-70, and 1874. This curve was also followed (more or less closely) by a group of diseases which in their seasonal distribution are most like scarlet fever. As regards erysipelas, puerperal fever, and rheumatism of the heart, the parallelism is almost complete, and there are plain indications of affinity in those of laryngitis, diphtheria, croup, and quinsy. During recent years, however, with declining mortality the rhythmic recurrence of scarlet fever has ceased to be perceptible in mortality-returns. Small-pox, which had been epidemic every four or five years, in London at all events, has also in recent years been less rhythmical in its prevalence. Measles has been epidemic at intervals which, as Munro and others have shown, average about two years in most towns, but may be longer or shorter; and whooping-cough at still less regular intervals of two or three years. These three diseases have no similarity to the scarlet-fever group in their seasonal curve. Another group, of which diarrhoea is the most prominent representative in this country, reach their annual maxima shortly after the highest temperature of the year is attained; their true relation being with the temperature of the soil. Diarrhoea often shows a curious tendency to biennial sequence of alternately high and low mortality; but on investigation, this, when it occurs, is usually sufficiently

explained by alternation of hot and cold summers. Whitelegge has shown that, whatever their causes may prove to be, these cycles, like the seasonal changes characteristic of each disease, are too definite to be regarded as due to accident. Nor are they likely to be purely mechanical, for they vary not only with each disease, and to some extent with locality, but also from decade to decade. There is reason to believe that they are connected primarily with variations in the quality of the contagium itself. As a general proposition, it may be stated that the years of greatest mortality are those in which both the prevalence and virulence are greatest. As regards scarlet fever, the case-mortality (that is, the percentage of fatal cases), if traced, year after year, seems to yield a curve which is almost parallel with that of the scarlet-fever death-rate. In the last decade, however, in London, with declining mortality this correspondence has been less exact. Statistics are wanting in respect of the case-mortality in measles, but occasionally, as in Sunderland in 1885 and Hanley in 1889, an exceptional virulence and severity of type are observed; and in these and other instances it has been found that for some ten years previously the usual biennial waves have gradually increased in destructiveness as shown by the records of mortality. Upon similar evidence it may be suspected that small-pox declined in average virulence, as it certainly did in average mortality, from about 1838 to about 1855, increasing again to a maximum in 1871, and thenceforward declining again until 1888 or 1889. Here, however, the question is further complicated by the dominant influence of vaccination, in addition to the social and climatic conditions which are obviously concerned in promoting or retarding epidemic extension.

SHIRLEY F. MURPHY.

PERICESOPHAGEAL ABSCESS.—See (ESOPHAGUS, Diseases of, p. 1114.

PERIOSTEUM, Diseases of.—See BONE, Diseases of.

PERIPHERAL (περί, around; and φέρω, I carry).—Of or belonging to the periphery or circumference, as opposed to the centre. The term is now applied chiefly to morbid conditions connected with nerves and nerve-trunks, as distinguished from the more central parts of the nervous system (see PARALYSIS). Peripheral may also be associated with the vessels, as distinguished from the heart, for example, *peripheral resistance*; and with the outer zone of the lobules of glandular organs, as, for instance, of the liver.

PERIPHERAL NEURITIS.—See NEURITIS, MULTIPLE.

PERIPROCTITIS (περί, around; and πρωκτός, the anus).—DEFINITION.—Inflammation of the connective tissue around the rectum.

ANATOMY.—The fat-bearing connective tissue beneath the peritoneum of the rectum is usually present only in moderate quantity; but posteriorly it becomes continuous, directly or through the meso-rectum, with a considerable layer of this tissue in front of the sacrum. Below the level at which the peritoneum disappears the periproctal connective tissue becomes continuous with that of the pelvis generally, in the male especially with that at the base of the bladder, around the vesiculae and

bladder, and in the female with that in the broad ligament.

The fatty tissue of the ischio-rectal fossæ is separated from the periproctal tissue by the considerable septum formed by the levator ani with the rectovesical fascia upon its pelvic, and the anal fascia upon its perineal aspect. This constitutes an obstacle, but not a bar, to the spread of inflammations from the pelvis to the perinæum.

ÆTIOLOGY.—Primary inflammation of the periproctal (as distinct from the ischio-rectal and circum-anal) tissue is very rare, except as the result of injury with infection. Such injuries have been inflicted by bullets, stabs, falls upon pointed objects, by catheters thrust through the urethra, or fish-bones, injection-tubes and bougies thrust through the rectum, by tears and cuts inflicted in the treatment of simple strictures of the bowel.

In the great majority of cases periproctitis is secondary to some other lesion. Most commonly this is ulceration of the rectum leading to infection and more or less rapid destruction of the rectal wall. Perforating ulcers, simple or malignant, of coils of small gut which adhere to the rectum, of the vagina, uterus, or bladder; sloughing of the vagina from prolonged pressure or intense infection; prostatic abscess and acute vesiculitis; sacral caries with abscess, are occasional causes. Pyæmic abscesses have, rarely, been found in this tissue; more often, though still rarely, an acute suppurative cellulitis has arisen as the result of infection from some wound, e.g. that after ligature of piles or even a fissure of the anus, two instances of which the writer has recorded in the *St. Bartholomew's Hospital Journal*. In all cases of general pelvic peritonitis and in many of pelvic cellulitis, the periproctal tissue is more or less affected, the rectum being commonly 'set' in the exudation, and sometimes perforated by a bursting abscess.

SYMPTOMS.—The symptoms of periproctitis can hardly be separated from those of the condition to which it is secondary. In *acute* cases, sense of weight and pain in the rectum, frequent calls to stool with passage of mucus and perhaps blood, tenesmus, fever—slight or grave—may be expected. Rectal examination should be carefully practised to detect the presence of a primary lesion and evidence of any swelling in the rectal wall or in its vicinity. In *chronic* cases, the bowel is usually contracted; ulceration, stricture, the dimpled orifice of a sinus, its course and source are the main points to look for. The neighbouring parts also must be carefully examined.

TREATMENT.—The exciting cause must be discovered and treated.

F. C. WALLIS.

PERITONEUM, Diseases of.—The morbid conditions of the peritoneum will be considered in the following order:—

Acute General Inflammation, p. 1193.

Acute Localised Inflammation, p. 1200.

Chronic Inflammation, p. 1201.

Hæmorrhage into, p. 1203.

Malformations of, p. 1204.

Morbid Growths of, p. 1204.

Tuberculosis of, p. 1204.

PERITONEUM, Acute Inflammation of.—

SYNON.: Acute Peritonitis; Fr. *Péritonite aiguë*; Ger. *Acute Bauchfellentzündung*.

ÆTIOLOGY.—It is now admitted on all sides that acute inflammation of the peritoneum is with few exceptions caused by the activity of micro-organisms. At the same time it must be remembered that bacteria can only effect this result under certain conditions. In order thoroughly to appreciate the rôle played by germs in producing peritonitis the philosophical maxim that 'every condition is causal' must be constantly borne in mind.

During the past few years numerous investigations have been undertaken with the view of discovering the organisms met with in peritonitis, and of establishing their exact relationship to the ætiology of the disease. The purely laboratory investigations must of necessity deal with peritonitis produced in animals, and when using facts derived from this source we must try and check the experimental results with the facts gathered from our observations on peritonitis met with in man.

In pre-bacteriological days Wagner had formulated with considerable precision the relations of the peritoneum to different influences. He proved the impunity of contact with air and of certain neutral fluids, and even of some decomposing fluids, provided they were in a quantity which could be easily absorbed by the peritoneum. These observations of Wagner were confirmed by an extensive series of experiments carried out by Grawitz. Grawitz showed that the introduction of saprophytes, even in enormous quantities, when diluted with normal saline fluid, did not harm the healthy peritoneum; also that the contents of the intestines in small quantities, and even in large quantities when sterilised by heat, could be injected into the peritoneal cavity without any harm resulting; finally, he found that well-known pyogenic organisms, such as the staphylococci and streptococci, could be introduced with impunity, provided the following four conditions were present, viz. (1) that the fluid used to dilute the cultures is innocuous to the peritoneum; (2) that the amount of fluid injected does not exceed the power of absorption of the peritoneum; (3) that the peritoneum is uninjured; (4) that no albuminous fluid, which very much favours bacterial growth, is present.

These experiments were repeated by Pawlovsky, who came to conclusions in many instances different from Grawitz. He found that minimal doses of *Staphylococcus pyogenes aureus* led to fatal peritonitis, and that the *Bacillus pyocyaneus* was especially fatal. The explanation of these contradictory results seems to lie in the fact that each experimenter was working with cultures of different virulence. This difference we are seeing constantly in relation to the human peritoneum; e.g. a woman when at work suddenly ruptures an irreducible umbilical hernia; the coils of intestine are bound up in a petticoat or similar garment; she is brought to the hospital and the intestines are washed, returned to the peritoneal cavity, and the patient recovers. On the other hand, a small punctured wound of the abdominal wall without any wound of the gut may cause fatal peritonitis. There is little doubt that in both cases ordinary pyogenic organisms obtain entrance, but they are quite different in their virulence. We must also bear in mind that the defensive powers of the peritoneum may differ markedly in different people.

While studying the effects of micro-organisms under the rigid conditions obtained in a laboratory, where the results are fairly definite and constant,

we are apt to lose sight of subtle differences that may exist in cultures of the same germ, differences that might come into play with great effect when laboratory discipline is once relaxed. From a consideration of the facts derived from operative surgery upon the abdomen and from experimental work we may formulate the conditions under which various micro-organisms will produce peritonitis:—

1. The presence of suitable medium for growth, that is, an albuminous substance such as lymph or blood.

2. The quantity of germs introduced into the peritoneal cavity from without or from the intestines, being in excess of that with which the absorptive power of the peritoneum can deal.

3. Damage to the serous membrane of the peritoneum. This may be of various kinds: (*a*) Necrotic action of the substance upon some part of the peritoneum, which will form a favourable nidus for bacterial growth, e.g. as in perforating gastric ulcer. (*b*) The diminution of absorptive power by the sealing up of lymph-spaces and capillaries. (*c*) An increase in the transuding power, as in the ordinary form of ascites or in cancer of the peritoneum. All these conditions are really causes of the ultimate result; and must be considered as well as the state of activity of the micro-organism. It seems undoubted that a germ which has been producing inflammation in the peritoneum of one person is much more vigorous in its attack if carried immediately to the peritoneum of another. This probably depends upon some property the germ itself has acquired. The best example of this is seen in puerperal septicæmia. The result of inoculation here produces an effect as definite and constant as the effect alluded to above as being obtained in laboratory experiments. It is in such instances as these that the organism stands out as being practically the sole cause of the disease. At any rate the conditions present take a very subordinate part.

Although peritonitis is nearly always associated with germs, we must not forget that certain chemical substances can produce the disease without the assistance of micro-organisms. Experimentally there is ample evidence on this point. Injections of croton oil, turpentine, and silver nitrate into the peritoneal cavity of animals have produced acute inflammation, sometimes of a hæmorrhagic type.

Non-bacterial peritonitis in the human subject is met with in the rupture of ovarian and other abdominal cysts; also in torsion of the pedicle of an ovarian tumour. A few cases have been reported of non-bacterial peritonitis caused by torsion of the spleen. In these cases no organisms can be found, at any rate in the early stages; of course, later on, when necrosis of tissue sets in, the bacterial invasion of the peritoneal cavity proceeds rapidly.

BACTERIOLOGY.—Although there is a great similarity in the pathological appearances and clinical signs of cases of acute peritonitis, yet the kind of organism exerts a very definite influence, and therefore it is important to consider the germs usually associated with peritonitis.

1. *Micrococci*.—(*a*) *Streptococci* are found in a large proportion of cases: according to Tavel and Lanz 75 per cent. (*b*) *Staphylococci* are seldom met with alone. As a rule they are associated with streptococci. (*c*) *Pneumococci* are found alone in about 2 per cent. The peritonitis in these cases tends to terminate favourably after flushing of the

peritoneal cavity. (*d*) *Gonococci*. There is no doubt that pure cases of peritonitis from the gonococcus do occur. The majority of cases in which gonococci are found are cases of mixed infection, streptococci playing a large part.

2. *Bacillus Coli Communis*.—Of the various germs found in the contents of the intestine, the *B. coli communis* is the most conspicuous. It is found in nearly all cases of 'perforative peritonitis,' that is, where the wall of the alimentary canal, whether stomach, intestine or vermiform appendix, is ruptured. Until quite recently the *B. coli communis* was regarded as the principal pathogenic organism in nearly all inflammations of intestinal origin. Tavel and Lanz showed that there were numerous species of this organism, which must be looked upon as a genus; and they threw doubt upon its being the cause of so much trouble. Veillon of Paris has produced good evidence for looking upon the *B. coli communis* as playing only a subordinate part, and has proved that certain anaerobic bacteria, which until now have not been properly isolated, are the true cause of many of the forms of appendicitis, especially those associated with acute gangrene, and those cases in which fetor and the formation of gas are special features. Veillon's work seems thorough and reliable and rids us of the great difficulty of explaining how a usually innocuous germ of the intestine like the *B. coli communis* should, without any apparent cause, suddenly develop such malignant properties. These anaerobic germs have been shown to be very destructive in their action upon tissues, causing intense inflammation resulting in more or less gangrene.

MODES OF ENTRANCE OF BACTERIA. —

1. *Wounds*, including (*a*) penetrating wounds of the abdominal wall, with or without injury to the viscera, and (*b*) injury to the viscera without any wound of the abdominal wall. 2. *Perforation by a foreign body*, including (*a*) those formed in the body, such as gall-stones, and enteroliths, &c., and (*b*) those taken in by the mouth. 3. *Operations on the abdomen*. 4. *Internal strangulations*, including volvulus, intussusception and internal hernie. 5. *Extension from an inflamed organ*, especially the intestine and vermiform appendix. 6. *Extension from a local abscess*, of which the most common forms are suppurative appendicitis and suppurative salpingitis. 7. *Perforation of hollow viscera*, as in gastric or duodenal ulcer, typhoid ulcer, &c.

Of these causes peritonitis, following surgical operations upon the abdomen, is becoming much rarer than formerly owing to improvements in operative technique. By far the most common cause in both sexes is appendicitis.

MODE OF ACTION OF THE BACTERIA.—The peritoneum presents a very large surface, being roughly equal in extent to the surface of the skin. If a normal saline solution be injected into the peritoneal cavity of a living animal, about one-tenth of the body weight is absorbed in an hour, or $2\frac{1}{2}$ times the body weight in a day; thus a man of 12 stone would absorb about 14 pints of saline fluid in one hour or 18 gallons in a day.

Conversely, if a substance be injected into the peritoneal cavity which leads to transudation, such as a concentrated solution of sugar, about $\frac{1}{10}$ of the body weight in fluid is exuded per hour. It is easy to imagine how rapidly the toxins elaborated by some organisms would be absorbed, and to account

for the very rapid onset of symptoms of septic poisoning in cases of peritonitis. In very acute cases the patient rapidly passes into a state resembling shock. It is not known whether this condition is due to the absorption of very rapidly formed toxins, or whether the inflammation of so extensive an area as the peritoneum may not produce, by reflex nervous action, a state similar to that of shock. We know that an acute inflammation of the whole of the skin—and it has already been pointed out that the area of the peritoneum is about equal in extent to that of the skin—has a profound influence upon the patient very much resembling that of shock.
